

Fig. 6 Punch or die force displacement diagram. (a) Extrusion of rod and can; (b) Die forging

Die Forging

The process of filling up the die cavity, which is constructed with upper and lower dies and coincides with the shape of the product, is called die forging [Fig. 4d]. Die forces increase with the die displacement [Fig. 6b] slowly at the beginning where the die is not filled yet and severely at the end where most of the die cavity is filled up and some redundant metal will be hanging out of the die cavity. We have to stop the die movement before the die pressure exceeds its proof stress to prevent die breakage. Filling up the die cavity soundly with material, suitable selection of billet shape is important. Height/diameter ratio of cylindrical billet, trimming of corner edge, giving small recess or taper to the end surfaces of the billet, are effective factors to be considered on the billet. Die design will be made by selecting suitable values of roundness of die corner edge, length of die land, die orifice angle, etc.

Alloys Used in Forging

Metal flow of forging is due to the ductility of material used. Soft material causes low stress on the die. So, ductility and low flow stress are essential characteristics of forging material. Characteristics of the material are directly related to the individual material's components, crystalline structure, temperature, strain, strain rate and so on. Table 1 shows characteristic mechanical properties

Table 1 Characteristic mechanical properties at room temperature and examples of applications

Material	Tensile strength MPa	Proof Strength MPa	Elongation %	Brinell Hardness HB _(10/500)	Characteristics and examples of application
1070-O	70	30	43	19	Excellent electrical and thermal conductivity

at room temperature, a convenient reference. In the case of cold forging, heat treatment of the billet is done before and during forging operation to arrange crystalline structure to increase or recover ductility. In the case of hot forging, billet is heated up during the forging operation to promise higher ductility and low flow stress of the material.

Examples of Forged Products

Cold forged products are shown in Figs. 7–11. Hot forged products are shown in Figs. 12–16. Figure 7 is of a connector of a railroad car, cold forged by Miyamoto Industry Co. from A7001. Formerly it was cast. To get higher strength parts, manufacturing technology was changed from cast to forging. Figure 8 is the housing of a hammer, cold forged by Miyamoto Industry Co. from A7001. Figure 9 is a part of an air conditioner for a motor car, cold forged by Miyamoto Industry Co. from A3003. Formerly two pieces were welded. To get higher reliability part welding was ceased. Backward extrusion of deep hole requires knowledge of the shape of the punch. Figure 10 is the housing of a maker pen, cold forged by Miyamoto Industry Co. from A1070. Process explanation is given later. Figure 11 is a hub for a spindle motor, cold forged by Miyamoto Industry Co. from A6061. Precision forging is needed to get a machining allowance of less than 0.15 mm. There are frequent model changes. Process explanation is given later. Figure 12 is part of an air conditioner, hot forged by Nichidai Co. from A1–10% Si. Counter punch was fitted to the end of the extruded part to get the same length of extruded parts. Figure 13 is piston-like, hot forged experimentally by Kubota Co. Figure 14 is a wheel for a truck, hot forged by Kobe Steel Co. from A6061. Wheels are occasionally forged or cast. Figure 15 is an automotive suspension, hot forged by Kobe Steel Co. from A7075. To understand suitable blank shape and forging temperature, simulation analysis by FEM was made. Figure 16 is a part for an aircraft, hot forged by Kobe Steel Co. from A7075. Its mass and x , y , z dimensions are 2.0kg and 566 mm, 236 mm, 49 mm respectively.

DESIGN

Estimation of Forging Pressure

The flow stress Y of the material is able to define as a flow stress p for friction free upsetting. Analyzed result by elementary slab method for upsetting pressure p considering frictional force acting on the end surface of the billet is

$$p = Y \left(1 + \frac{\mu d}{3h} \right) \quad (5)$$

Herewith μ , d and h denote Coulomb's frictional coefficient, diameter of billet and height of the billet respectively. In some occasional cases, it is confirmed that $\mu = 0.03\text{--}0.05$ for well lubricated surfaces of cold forging products. It is easy to understand that in case of $\mu = 0$, p coincides with Y , then

$$p = Y \quad (6)$$

In the case of upsetting of thin plate under the condition of μ is not zero, as the ratio of d/h becomes larger, so higher pressure will be needed to cope with frictional force which comes from terms of $\frac{\mu d}{3h}$. Former equation can be rewritten in the form of

$$p = cY \quad (7)$$

or

$$\frac{p}{Y} = c \quad (8)$$

c is called constrain factor indicating how much forging pressure will be needed based of flow stress Y . c is determined by the product's shape and is independent from characteristics of individual materials.

Specific rod and can extruding pressure p/Y , analyzed by upper bound approach, are shown in Fig. 17.^[3] Solid and dotted lines correspond to specific pressure for forward extrusion of rod and backward extrusion of can respectively. Two lines are for frictional conditions of friction free and sticking. For a certain lubrication condition, specific extrusion pressure will be read from the position on Fig. 17 between solid and dotted lines depending on lubrication condition on the reduction in area of horizontal axis of the figure. Actual forged products have complicated shapes as shown in Figs. 7–16. Specific pressure for complicated shape products, we have to calculate them individually. However it is possible to refer the results for similar shapes which are published in a great amount of technical reports and books.^[4–10]

After knowing the value of c , we have to estimate Y to be multiplied. For steady state motion problem of sheet drawing, R. Hill^[11] had proven that if there is no frictional forces on die surfaces, the mean plastic work per unit

Fig. 17 Relations between theoretically analyzed specific extrusion pressure and reduction in area^[3]

volume is equal to the drawing stress p . Now for a non-hardening material, obeying the Levy–Mises yield criterion, the work per unit volume is equal to $Y \int d\epsilon$, where $\int d\epsilon$ equivalent strain. We can therefore define a mean equivalent strain for sheet drawing equal to p/Y . Let us assume that this can be extend to the forging problems. Now it can be said that equivalent strain is equal to p/Y and p/Y is equal to c . Using flow stress and strain curve, say Fig. 2 for pure aluminum, mean flow stress Y_m can be calculated as

$$\int_0^c \frac{Y d\epsilon}{c}. \text{ The result of the multiplication } c \text{ and } Y_m \text{ is theo-}$$

retically estimated pressure p . For any ductile materials, this method can be applied if we know individual flow stress–strain curves. For further study of non-steady state motion problems, equivalent strain is defined as.^[12]

$$\int d\epsilon = \int_{h_2}^{h_1} \frac{p}{Y} \cdot \frac{dh}{h} \quad (9)$$

and it was confirmed that this equation promises good estimation of equivalent strain.^[13]

Defects

Underfill and Overlap of the Skin

It is desirable to fill up the die cavity perfectly with material without underfill. But sometimes underfill is observed from the reasons of unsuitable billet shape, trapped air at die corner, excess lubricant on billet surface and so on. By choosing an appropriate billet shape, underfill defect can be averted. Appropriate billet shape can be designed by trial and error. Recently computer simulations were applied to predict

Fig. 18 Analyzed velocity distribution for forging of video drum

appropriate billet shapes. If it is difficult to avert a defect by choosing appropriate billet shape, we have to add one more forging operation. Figure 18 is an example of velocity distribution during the forging operation of a hub spindle motor (Fig. 11) estimated by FEM programme. It is helpful to predict underfill or overlap of the material during deformation.

Dead Metal and Skin Inclusion

Sometimes some part of the material is apart from the major part of the material and is split in two, along with the process going on and left from deformation. The split part is called dead metal. Dead metal is observed, for example, in the die corners, Fig. 19a, or concave place, Fig. 19b. If die or punch displacement is not big, dead metal does not build up but skin inclusion is observed initiating dead metal.

Dead metal and skin inclusion are initiated by too much velocity discontinuities in the deformation zone and less ductility of the material. Preparation of roundness on die corner edge or giving moderate change of die profiles are helpful to bring smaller value of velocity discontinuity, and consequently are effective methods to avoid dead metal or skin inclusion.

Cracking

If ductility of the material is not enough, cracking will occur at the place where large shearing or tensile stress is acting. Those stresses are initiated by velocity discontinuity during plastic metal flow and/or stresses suffered from outside. Criteria of cracking can be expressed as a function of strain and mean stress. Sometimes counter pressure is added to deformation region to prevent cracking by means of a higher

mean stress. For example, in the case of rod extrusion [Figs. 4a and 19e], internal compressive and tensile stresses are acting at the outer and central portions of the extruded rod. If impact extrusion is made, body force of the extruded part is pulling the deforming zone. As a result, tensile stress is increased at the central portion of the rod, and cracking is sometimes observed. The crack observed at the central portion of the rod is called a Chevron crack [Fig. 19c]. We know some examples of preventing Chevron cracks by reducing the extruding speed to reduce tensile stress on the central portion of the rod which was caused by body force. Heating up the material is effective to improve ductility. Annealing heat treatment before and during cold forging operations aims to increase ductility of the material.

Contraction

It is natural to think that metal flow which occurs during forging operation must be the way of minimum energy dissipation rate. For this reason, at the end of forging operation, where billet length became short, some part of metal surfaces comes apart from the die surface and makes contractions where it has kept contact with die surface beforehand. Contraction^[6,7] can be seen on the central portion of the billet end surface [Fig. 19d] for rod extrusion, on the corner of billet bottom [Fig. 19e] for backward extrusion of can, or the central wall surface of billet for combined extrusion of can and can [Fig. 19f]. The way of getting rid of contractions is to keep billet length long, to give a larger corner radius on the punch or die to allow a wider deformation zone, or to fit a counter punch to the end of the extruded parts to give pressure to restrict the natural energy minimum metal flow.

Fig. 19 Forging defects, 1. Punch, 2. Backup punch, 3. Counter punch, 4. Container, 5. Die, D. Dead metal, S. Skin, C. Contraction. (a) Dead metal; (b) Skin inclusion; (c) Chevron crack; (d), (e), (f) Contraction

Grain Growth

Grain growth is observed at the heat treated place of a certain amount of strain. Forged parts have a variety of strain, so the possibility of grain growth during heat treatment is high. Large grain is poor in mechanical properties. To get a fine anodic oxidation process, uniformly distributed small size grain of 30 μ m in diameter is desirable.

Orange Peel

Too much lubricant causes orange peel appearance on the surface of the forged products and loses smooth and bright surface.

Forging Temperature

The temperature of the materials to be forged is determined by the shape and size of the products, ductility and strength of the materials etc. Generally speaking, hot forging is applied to brittle- or high-strength materials or complex shaped products. Recommended forging temperature is shown in Table 2.

Sometimes the die is heated up during hot forging operations to get little drop in billet temperature when billet is mounted on the die. An approximate pre-heating temperature will be 80% of the billet's temperature or

Table 2 Forging temperature

Materials	Forging temperature (°C)
1070	315–405
1100	315–405
2014	420–460
2017	420–470
2024	420–470
3003	315–405
5052	425–470
5056	300–500
6061	300–500
6063	350–450
7075	350–450

50°C lower than the billet temperature.^[14] Ninety percent of the energy used for forging will dissipate as heat. The heat elevates the forged product's temperature and sometimes the temperature of the forged product is higher than the billet's temperature. On the other hand, billet temperature is decreased because of the heat sink from billet to die when billet is mounted on the die. Higher materials temperature brings low flow stress and more ductility, but initiates grain growth of the material. Lower material's temperature brings little or no oxidation and

precision dimension but brings higher flow stress and less ductility which initiates cracking of die and/or products. For some alloys, flow stress and ductility are very sensitive to the temperature. So, selection of forging temperature should be made carefully. Figure 20 shows the temperature distribution on A-A cross sectional area of automotive suspension parts, Fig. 15, to be produced by hot forging. To obtain precision data of flow stress for the material at high temperature and strain rate, upsetting test on press machine creating high strain rate was carried out. Using the results, the FEM analysis was done.^[15] Checking analytical results of temperature distribution, forging temperature was determined. Exactly speaking similarity law is not able to be true to the problem of three dimensional hot forging deformation problem. The temperature of a small blank changes very quickly. Different lubricants have to be selected by temperature. Warm forging between 150°C and 200°C is applied for the purpose of reducing viscosity of the lubricant to get smaller frictional resistance by warming up the lubricant.

Application of Counter Punch

Heat radiation part used on a personal computer, Fig. 21, bottom, is obtained by the forward extrusion accompanied by a counter punch. Counter punch is fitted against extruding rods and supported by a hydraulic cylinder of 300 kPa. Better product, Fig. 21 bottom, which have almost the same length of extruded rods compared to the product extruded without counter punch, Fig. 21 top. Product of Fig. 12 was extruded with counter punch of 40–50 kN. Scatter of height of fin was less than 0.5 mm. A product which extruded without a counter punch, has 20 mm difference in height of extruded fin.

FORGING PROCESS

In most cases, shape, dimensions and material of the product to be forged are determined by the customer. Process design is done to forge it without defects.

Backward Extrusion of Housing of Maker Pen

A blank was pierced from thick sheet metal of pure aluminum A1050. The process is as follows: Piercing of blank → Lubricating → backward extrusion of tube at room temperature → trimming and rolling of tube end → degreasing → drying → prepainting → drying → painting → drying → over coating → drying → inspection → finishing.

Blank (Fig. 22, top) has a recess of 0.5 mm deep on one end surface and curved surface on the other end. Zinc stearate is used as a lubricant. Extruded product is shown in Fig. 22 bottom. To get exactly the same length of tube after trimming, the extruded tube must have the

Fig. 20 Temperature distribution estimated by FEM for hot die forging of automotive suspension, Fig. 19^[15]

Fig. 21 Heat sink (A1070) forged by Miyamoto Industry Co

[illegible]

same temperature. Tool set up is shown in Fig. 23. Punch 1 and die insert 3 are made from high speed tool steel M2 = SKH51 of hardness of 62 HRC and 58 HRC respectively. Container 4 is made from cemented carbide. The punch can be used 2 million times. Thickness of the tube bottom is 3.1 mm. To forge a thinner bottom tube, less than 3.1 mm, the die life was short. Five pieces of tube can be produced per minute.

Cold Forging of Video Drum

Pierced blanks (Fig. 24) are sorted by mass into five classes. Sorted blanks of 70 ± 0.25 g are used as materials for Fig. 25. Tool set up is shown in Fig. 26. Punch 1 and 2 and punch cover 3 are made from alloy tool H13 = SKD61 with hardness of 53 HRC. Die insert 4, ejector 6, and shrink rings 9 and 10 are made from alloy tool steel D2 = SKD11 with hardness of 55 HRC. Tool can be used about 50,000 shots.

Cold Forging of a Hub for a Personal Computer

Figure 27 bottom is a drawing of a spindle motor hub for a personal computer to be forged. Forging process is as follows: Extruded bar → drawing → cutting → annealing → lubricating → sorting by mass → cold forging on

Fig. 24 Billet for video drum

Fig. 25 Drawing of video drum

crank press, capacity of 100 t → piercing, Fig. 27 top → annealing → lubricating → cold forging on knuckle joint press, capacity of 150 t → heat treatment T6 → cleaning.

Material A2011-0 is select as is high strength and cut easily. Blank is sorted by mass. Depending on hub size blank's mass is between 12–15 g, but blank's mass scatter is less than ± 0.05 g. Tool set up is shown in Fig. 28. Punch 1 is made from alloy tool steel H11 = SKD11. Die 4 and 5 is made from high speed tool steel M2 = SKH51. Punch can be used 50,000 shot. Five thousand hubs were forged per month. To get near net shape forged product (Fig. 27 bottom), it is important to get suitable pre-forged product's shape (Fig. 27 top). Model is changed frequently, and each time, suitable pre-forged shapes have to be designed by experience or computer simulation as soon as possible.

PRESS

Mechanical press, hydraulic press or special purpose press are used for aluminum forging. After selecting the type of press machine, then press capacity, length of ram stroke, and automatic operating methods are checked. Productivity is dependent on the number of ram strokes per minute.

Fig. 26 Tool set up for die forging of video drum, Miyamoto Industry Co. 1. Punch, H13 = SKD61, 53 HRC; 2. Punch, H13 = SKD61, 53 HRC; 3. Punch cover, H13 = SKD61, SKD61, 53 HRC; 4. Mechanical Press

Crank press is popular as a mechanical press. It has simple mechanism but has high productivity and is convenient for multipurpose usage. As mechanism is simple, machine trouble is infrequent and automatic operation is easy. Crank press is used for both cold and hot forging. Especially in the case of hot forging, shorter contact time between hot forging material and die is desirable to escape warm up of die temperature. To keep die temperature low is good for die material because the strength of die material is poor at elevated temperature.

Link Press

Link press, Fig. 29, enables large force at the end of ram stroke, near bottom dead center, compared to a crank press. In the case of cold forging, it is said that pushing forging material time a little bit longer to the die at the end of the ram stroke is good to get near net shape product. If contact time is longer, the die profile will be copied to material better. Hub shown in Fig. 11 was forged on a link press at room temperature.

Fig. 29 Link press produced by Komatsu Ltd

Hydraulic Press

Hydraulic press is large in capacity, long in ram stroke movement and easy in ram speed control. Hydraulic press is best to control die movements.

Special Purpose Press Machine

For mass production, such as the housing of a marker pen, Fig. 10, special purpose press machine is used to manufacture it automatically.

Ductility of aluminum alloy is sensitive to strain rate sometimes, so a press that has easily changed speeds is recommended for aluminum forging.

CONCLUSION

A trial experimental engine piston-like product is shown in Fig. 13 made from Al-13% Si. Al-13% Si powder of 400 μm diameter is produced by a spinning water atomization process. Powder is compacted to blank and sintered. Hot forging was done at 793K with graphite as a lubricant. The drum for a video is cold forged experimentally using an extruded rod of aluminium powder of Al-19.8% Si-2.0% Cu-0.9% Mg. Tensile strength, elongation and hardness of forged drum are 402 MPa, 2.7% and 79.5 HRB respectively.

If precision forging technology makes it possible to manufacture higher strength aluminum alloys, the application of aluminum to automotive or other industries will be accelerated.

Friction Stir Processing: Effect on Microstructure and Mechanical Properties in Cast Aluminum Alloys

Murat Tiryakioğlu and Nelson Netto

University of North Florida, 1 UNF Drive, Jacksonville, FL, 32224, United States

Abstract

Microstructural and mechanical data from the literature of friction stir processed (FSPed) cast aluminum alloys were reanalyzed. Results indicated that friction stir processing (FSP) produced more homogeneous microstructures, with finer eutectic Si particles, grains, and intermetallics. However, a relationship between microstructural measures and process parameters could not be established. Regardless of the resultant microstructure, structural casting defects, i.e., pores and oxide films, were reduced in size or completely eliminated after FSP. Consequently, ductility and fatigue life were drastically improved by FSP. Quality index analysis showed that some FSPed specimens have a higher structural quality than aerospace and premium quality castings, and can be used to determine the intrinsic properties of cast aluminum alloys.

Keywords: Defect elimination; Ductility improvement; Fatigue life; Microstructural characterization; Quality index.

INTRODUCTION

In friction stir welding (FSW), a rotating, nonconsumable tool is used to produce plastic deformation and frictional heating to join two metallic components.^[1,2] The tool, consisting of a pin and a shoulder, is plunged between two plates while rotating, until the shoulder gets in contact with the outside surface of the workpiece. Subsequently, the tool is forced along the line of the joint, while the shoulder remains in contact with the workpiece. Friction stir processing (FSP) is a technique derived from FSW^[3,4] and is shown schematically in Fig. 1. In FSP, the purpose is not welding two pieces but modifying the local microstructure in a single workpiece. This microstructural modification has been stated as the reason for improvement in mechanical properties, such as tensile properties and fatigue life.

Aluminum castings are known to have major structural defects, such as pores and entrained oxide films.^[5–7] Consequently, fatigue life^[8–13] and tensile properties, especially elongation,^[5,14–22] are reduced to a great extent due to the presence of these structural defects. The elimination of these defects has important ramifications on the use of castings. The literature for cast Al-Si-Mg alloys attributes the refinement of Si particles and defect elimination or healing by FSP as possible reasons for the enhancement of mechanical properties.^[23] If FSP is capable of eliminating/healing those defects, it becomes finally possible to determine intrinsic properties of these alloys. This study is motivated by the potential of FSP to heal casting defects.

BACKGROUND

FSP Parameters

There are two important process parameters for FSP: tool rotational rate, ω (rpm), in clockwise or counterclockwise direction and tool transverse speed, V_t (mm/min).^[2] The advance side (AS) is where the rotational tool is in the same direction of the advancing movement and the opposite side is called retreating side (RS).^[25]

The pin geometry is a critical parameter to determine the material flow during FSP process. The FSP tool is composed of a pin and a shoulder. During the process, the tool has two main purposes: (i) heat the material by friction and (ii) flow the material.^[1,2] Additional heat comes from internal friction of the material due to deformation.^[1,26] The heat from the process generates a temperature increase of 400°C–500°C,^[1,27] and consequently softens the aluminum alloy, bringing it to malleable state and promoting the flow from the front to the back of the tool and around the pin.^[1,26] The flutes in the tool can promote and amplify the material flow around the pin.^[26] The threads on the pin tend to move the material down along the pin, and once the material reaches the bottom, the pin geometry will move the material up and away from the pin.^[1,26] Usually, the tool is held at a tilt angle of 1°–3° to increase the forging action during the FSP process.^[28] The shoulder also provides the confinement of the heated material during the process.^[1] If downward force or heat input is insufficient, the flow of plasticized metal is not

Fig. 1 Schematic illustration of FSP^[24]

appropriate, a tunnel defect, i.e., continuous pore along the traverse direction, can form.^[26,29] More details about the process can be found in the excellent review provided by Mishra and Ma.^[1]

The Effect of Process Parameters on Microstructural Evolution

The FSP parameters have a strong effect on the material flow and the temperature distribution within the workpiece. Consequently, microstructural evolution is sensitive to the levels of FSP parameters. The evolution of the average equivalent diameter of Si eutectic particles, d_{Si} , was investigated in cast Al-Si alloys, including A356,^[30–31] A319,^[34] and A390.^[35] The results from four independent studies on these three alloys are presented in Fig. 2, which shows

the effect of rotational speed on d_{Si} . Note that there is no consistency between the studies on how average Si particle diameter evolves with increasing rotational speeds, other than the general observation that FSP reduces d_{Si} . Transverse speeds, which are also indicated in Fig. 2, affect d_{Si} differently for different alloys and/or at different levels of ω . For A319, increasing V_t from 12.5 to 20 mm/min produces larger Si particles. In contrast, increasing V_t from 10 to 20 mm/min in A390 alloy castings results in finer Si particles. Because these observations were made at vastly different rotational speeds, i.e., 300 rpm for A319 and 1500 rpm for A390, there is a strong possibility that there is an interaction between V_t and ω . Hence, the effect of V_t probably depends on the level of ω .

In several studies,^[30,36] the change in grain size, d_G , after FSP was investigated. In all studies, it was reported that friction stir processed (FSPed) samples contained fine grains without any dendritic structure remaining from the as-cast condition. The reduction in average d_G in cast A356 alloy with rotational speed is presented in Fig. 3. Note that grain size is reduced approximately an order of magnitude for all FSP conditions. Moreover, increasing the rotational speed reduces the average grain size further. The reduction in grain size after FSP was also observed in cast Al-Cu alloys. Kapoor et al.^[36] investigated the grain size before and after FSP for cast A206 alloy. The grain size results reported by Kapoor et al. were reanalyzed in the present study and found to follow the lognormal distribution, which is consistent with previous findings reported in the literature.^[37] The density function, f , of the lognormal distribution is written as

$$f(d) = \frac{1}{d\sigma\sqrt{2\pi}} \exp\left[\frac{-(\ln(d) - \mu)^2}{2\sigma^2}\right] \quad (1)$$

Fig. 2 The evolution of diameter of Si particles with tool rotational speed, ω , for different cast Al-Si alloys including A356^[30,33] A319,^[34] and A390^[35] FSPed at various transverse speeds

Fig. 3 The change in grain size in A356 cast aluminum alloy with rotational speed during FSP^[30]

where σ and μ are the shape and scale parameters, respectively. The lognormal analysis results are presented in Fig. 4. Note that both axes are logarithmic so that both distributions can be presented in the same plot. As in A356 castings, FSP reduces d_G in A206, but the level of reduction is higher than in A356 and is approximately 2 orders of magnitude.

The Effect of Multiple Passes

In a majority of the studies on FSP, the effect of process parameters on the microstructure was characterized after

a single pass. However, a method to further modify the microstructure in Al castings via FSP is having multiple passes. Baruch et al.^[24] investigated the evolution of microstructure in A356 castings with each FSP pass. They used a rotational speed of 600 rpm and a transverse speed of 12 mm/min and performed two and three passes with 100% overlap from the previous zone. The average Si particle diameter without FSP was found to be 5.50 μm . After FSP, the average d_{Si} size was reduced to 1.17 μm after the first pass, and further reduced to 0.86 and 0.80 μm after two and three passes, respectively. These results were not confirmed by Ma et al.,^[33] who found that the average Si particle size obtained after a single pass remained unchanged after multiple passes at $\omega = 700$ rpm and $V_t = 203$ mm/min with a triflute tool.

Because Si particle size has been found^[38–40] to also follow the lognormal distribution, Si particle size distributions were inferred from the results of Baruch et al., which are presented in Fig. 5a. Similar results were reported^[34] for A390 alloy castings. In a recent study,^[31] however, Si particle size was found to increase with each pass, as evidenced by the shift of lognormal distributions to the right, when $\omega = 700$ rpm and $V_t = 50$ mm/min. The coarsening of Si particles with each pass can be attributed to a higher level of heat generation because of higher ω and V_t values than those used by Baruch et al.

In all studies on cast Al-Si alloys, it was reported that the microstructure got progressively more homogeneous after each FSP pass. In a recent study on the A356 aluminum alloy, Woertz^[32] reported that Si particles moved to

Fig. 4 Grain size distribution of A206 and FSPed samples

Fig. 5 Probability density functions of Si particle equivalent diameters after one, two, and three passes: (a) Baruch et al.; (b) Netto et al.

“previously unoccupied regions” after FSP and Si particle clusters were dispersed so that their spacing became more uniform. Netto et al.^[31] quantified the microstructure of A356 alloy castings by using the nearest neighbor distance, L_{nn} , as measured from the centroid of each Si particle. The authors found that (i) L_{nn} followed the lognormal distribution and (ii) with each FSP pass, L_{nn} distribution shifted to right, as shown in Fig. 6. Hence, the microstructure became more homogeneous with increasing L_{nn} after each pass.

Effect of FSP on Casting Defects

Structural defects from cast aluminum alloys, such as pores and oxide films, can affect the mechanical properties significantly.^[41] Specifically, the size distribution of structural defects can be linked to the statistical distribution of fracture properties, such as fatigue life.^[9,42] If these extrinsic structural defects can be minimized or even eliminated, the intrinsic mechanical properties and performance of aluminum castings can be determined. It is the

Fig. 6 Probability density functions of the nearest neighbor distance for Si particles in the three FSP microstructures

authors' opinion that defect elimination and the possibility of determining the intrinsic properties of cast aluminum alloys is where the largest impact of FSP can be made.

The change in pore sizes in cast aluminum alloys after FSP has been reported in many studies.^[23,35,36,43] Overall, authors reported that FSP resulted in a significant decrease in the size of the pores in castings. The degree of pore healing is affected by the initial size of pores. Ma et al.^[44] studied the effect of FSP in A356 castings with initial pores of 1–2 μm in diameter. After FSP, no pores could be observed in the stir zone. Similar results were reported in A206 alloy castings by Apelian et al.^[23] and Kapoor et al.^[36] Mahmoud et al.^[35] found pores with sizes ranging from 10 to 150 μm in the as-cast A390 alloy samples. After FSP, only micropores of 1–2 μm were visible. Moreover, the size of the micropores were on the order of grain size, which was found to be 3 μm .

Along with Si eutectic particles, constituents such as the Fe-bearing β -platelets (Al_3FeSi) are also altered during FSP. Cao and Campbell^[45–47] found that Fe-bearing constituents, including β -platelets, nucleate on oxide films that get entrained into the melt from the ingot or during mold filling. DeBartolo and Hillberry^[48] demonstrated that the size distribution of β -platelets can be taken as the flaw size distribution in wrought aluminum alloys. Hence, the number density and size of β -platelets are an indication of oxide film entrainment (damage) to liquid aluminum. Because the length of β -platelets, L_β , was shown^[48] to also follow the lognormal distribution, the results of Kapoor et al.^[36] were reinterpreted statistically. The fitted lognormal distributions for L_β before and after FSP

are presented in Fig. 7. Note that FSP reduces the sizes of the largest β -platelets, i.e., largest oxide films, whereas the sizes of the smallest β -platelets (films) are not altered.

It is clear that FSP significantly reduces the sizes of pores and constituents, or oxide films on which they nucleate, in castings. Consequently, the mechanical properties of FSPed cast aluminum alloys are expected to be superior to those that are tested without FSP. The extent of improvement in tensile and fatigue properties is addressed next.

ANALYSIS OF THE MECHANICAL DATA FROM LITERATURE

Tensile Properties

The damaging effect of casting defects on the tensile strength and elongation (e_f) of cast aluminum alloys has been reported in many studies.^[5,14,15,17,22,49–52] Elongation is the property that is most adversely affected by casting defects. It has been reported^[53] that cast Al-Si alloy specimens do not neck during tensile testing, even when they are excised from aerospace castings.

Failure in metals is the outcome of two competing modes: plastic deformation and fracture.^[54] If the stress necessary for permanent deformation is lower than the stress necessary to permanently separate atoms, plastic flow occurs instead of fracture. From the point of view of maximizing resistance to failure, plastic deformation is a more preferable “failure” mode, since plastic flow preceding fracture markedly increases the energy accompanying

Fig. 7 The distribution of lengths of β -platelets before and after FSP in A206 castings

the fracture. The energy absorbed per volume by a tensile specimen, which is commonly also referred to as the strain energy density, can be found by the area under the true stress–true strain curve. Alexopoulos and Tiryakioğlu^[55] analyzed true stress–true strain curves in A357 alloy castings and showed that elongation to fracture is an excellent of the strain energy density. Similar results were reported for A206 aluminum alloy castings.^[17]

Tiryakioğlu et al.^[18–20,41,56] proposed the concept of ductility potential for cast aluminum alloy, to develop a new quality index. The author used tensile data from aerospace and premium quality castings to determine whether there is a relationship between maximum elongation, $e_{F(max)}$, and yield strength, σ_Y . They reported that maximum elongation, i.e., ductility potential, can be estimated by^[41]

$$e_{F(max)}(\%) = \beta_0 - \beta_1 \sigma_Y \quad (2)$$

where β_0 and β_1 are alloy-dependent coefficients, and are 36.0 and 0.064 MPa^{−1} for cast Al–Si–Mg alloys, respectively. Based on the concept, the quality index, Q_T , is found by

$$Q_T = \frac{e_F}{e_{F(max)}} = \frac{e_F}{\beta_0 - \beta_1 \sigma_Y} \quad (3)$$

Note that Eq. 3 represents the ratio of energy absorbed during deformation to energy that would be absorbed if deformation was not interrupted prematurely by fracture due to casting defects.

As discussed previously, there is strong evidence in the literature that FSP reduces the sizes of casting defects significantly. To determine the extent of this effect on tensile

properties, 11 datasets for the literature were collected and reanalyzed by using the quality index, Q_T . The yield strength–elongation data from these datasets are presented in Fig. 8. Note that the ductility potential for Al–Si–Mg alloy castings is also indicated, and there are several data points that exceeded the ductility potential line. These results are summarized in Table 1, in which the number of tensile results in as cast (no FSP), n_{ac} ; the number of tensile results after FSP, n_{FSP} ; and the corresponding maximum Q_T values are listed. Note that in every dataset, a significant increase in Q_T was achieved. Moreover, in seven datasets, the maximum Q_T after FSP was at least 0.90, and in five datasets, it exceeded 1.00. Hence, structural quality levels well in excess of aerospace and premium quality castings could be obtained by FSP although the starting as-cast material had Q_T levels of 0.10 or less. These results provide compelling evidence that FSP heals casting defects to a great extent, if not completely.

The micrographs showing the microstructure below the fracture surfaces in as-cast and FSPed A356 alloy tensile specimens are presented in Fig. 9.^[43] The as-cast specimen that fractured at $e_F = 3\%$ exhibited no necking. Moreover, secondary cracks under the fracture surface are visible. The fracture surface is tortuous, which indicates that multiple cracks were probably formed from entrained oxides during deformation, which later coalesced and led to final, premature fracture. In contrast, the FSPed specimen showed no secondary cracks below the surface and the specimen did not neck prior to fracture. Additionally, some Si particles below the fracture surface seem to have been cracked. However, these cracks did not extend into the aluminum matrix. Consequently, elongation was 31%, which was above the

Fig. 8 Yield strength–elongation plot for as-cast (no FSP) and FSPed specimens

Table 1 Details about the datasets from literature that were reevaluated in this study

Dataset	Alloy	n_{ac}	n_{FSP}	Reference	Notes	Max Q_T (No FSP)	Max Q_T (FSP)
1	A356	1	10	[57]	No heat treatment	0.10	1.10

ductility potential previously estimated for these alloys, as indicated by the Q_T value (1.13) exceeding 1.0.

The Effect of FSP on Fatigue Life

It is well known that fatigue failure process has three stages: (i) crack initiation, (ii) crack growth, and (iii) rapid fracture.^[2] In many studies on fatigue behavior of cast aluminum alloys, cracks were observed to start propagating from casting defects almost immediately after fatigue testing started.^[61–64] However, Jiang et al.^[65] found that crack initiation phase can be as high as ~60% of total fatigue life (N_f) in A356 aluminum alloy castings. They stated

that any improvement in N_f will most likely be due to longer initiation phase because once the crack reaches a certain size, crack propagation rate was found to be similar in specimens with varying duration of crack initiation phases. Hence, fatigue life in Al alloy casting is governed by the size and shape of defects,^[2,9–13,58,66,67] namely, pores and oxides films, and fatigue strength decreases as defects become larger.^[2,67]

In the high cycle fatigue region, the change in fatigue life with stress amplitude, σ_a , can be expressed by the Basquin law:^[68]

$$\sigma_a = \sigma'_f N_f^b \quad (4)$$

Fig. 9 Micrographs showing the area below fracture surfaces^[43] and their corresponding tensile properties in as-cast and FSPed A356 alloy casting tensile specimens

where σ'_f is the fatigue strength coefficient and b is the elastic exponent (also known as the Basquin exponent).^[69] Both Basquin parameters are strongly affected by the material,^[70] specimen geometry^[71] as well as the type of test conducted.^[72] According to Kun et al.,^[70] the Basquin exponent is a measure of the degradation taking place at the microlevel. Based on this concept, Özdeş and Tiryakioğlu^[13,69] showed that b is affected strongly by structural quality and can be estimated from Q_T in aluminum alloy castings.

Because FSP increases the structural quality by healing casting defects, N_f can also be expected to increase significantly after FSP. To test this hypothesis, data published for axial fatigue^[73] for A356 and bending fatigue for A357^[60] and A206^[36] alloy castings were reanalyzed. Results of the reanalysis of fatigue life data are presented in Wöhler diagrams presented in Figs. 10–12, respectively, with estimated Basquin parameters for each condition. Note that in all three datasets, fatigue life is significantly higher for FSPed specimens than for as-cast at any given stress amplitude. Moreover, estimated b values are higher (less negative) for FSP, consistent with the statement by Kun et al.^[70] and the findings of Özdeş and Tiryakioğlu.^[13,69]

Micrographs of fatigue specimens below the fracture surface of A356 aluminum alloy castings are presented in Fig. 13.^[73] Similar to fracture surfaces of tensile specimens shown in Fig. 9, secondary cracks are visible below the fracture surface of as-cast specimen. In the

FSPed specimen, fractured Si particles that did not create any secondary cracks were also observed. The secondary cracks can be attributed to the presence of oxide films within the casting. During FSP, these oxide films are healed due to severe deformation, and consequently, no secondary cracks appear in FSPed specimens. This is further supported by the fracture surfaces of A356 alloy castings presented in Fig. 14.^[73] The fracture surface of the as-cast specimen is tortuous, and the areas of sudden fracture without any signs of ductility are visible. In the FSPed specimen, fracture surface is flat but shows high levels of ductility all around the investigated area. Without sudden, premature local fracture, fatigue initiation can be expected to last long and dominate the overall fatigue life.

CONCLUSIONS

- FSP, in general, reduces the sizes of Si eutectic particles, grains, and intermetallics in all cast aluminum alloys. Moreover, the resultant microstructure is always more homogeneous after FSP than before. However, it is not possible to link the levels of FSP parameters to the final microstructure quantitatively at this time.
- FSP reduces the sizes of casting defects significantly. Pores are healed and frequently eliminated completely during FSP. Constituents, namely, Fe-bearing β -platelets that nucleate and grow on oxide films, are reduced in

Fig. 10 Wöhler diagram for axial fatigue of A356 specimens with and without FSP^[73]

size significantly. Hence, there is a distinct increase in the structural quality of the material during FSP of aluminum castings. Consequently, mechanical properties, such as elongation and fatigue life, are improved to a great extent.

Fig. 14 Fracture surface of as-cast specimens (a and b) and friction stir processed specimens (c and d)^[73]

- In FSPed Al-Si-Mg alloy castings, the quality index, Q_r , was found to exceed 1.0. Therefore, FSPed Al-Si-Mg alloy castings have a higher structural quality than the aerospace and premium quality castings. Moreover, FSPed Al-Si-Mg specimens can be used to determine the intrinsic properties of these alloys.
- There is strong evidence that oxide films that get entrained into aluminum castings are healed during FSP, as evidenced by the lack of secondary cracks near the fracture surfaces of tensile and fatigue specimens.

Friction Welding of Al₂O₃P/6061 Aluminum Alloy Composite to 5052 Aluminum Alloy

K. Kato and H. Tokisue

College of Industrial Technology, Nihon University, Tokyo, Japan

Abstract

6061 aluminium alloy matrix composite containing 20.5 vol% particulate alumina and 5052 aluminium alloy were welded using a brake type friction welding machine. The microstructures and mechanical properties of the friction welded joints were investigated. The mechanically mixed regions and the alumina particles which had moved to the other part of the composite alloy were observed clearly on the weld interface. The hardness at the weld interface showed higher values than those of the base metals. The variation of hardness on the composite material side was not very significant, but a softened area could be seen in the heat affected zone of the 5052 aluminium alloy side and recovery to the same level of hardness as that of the 5052 aluminium alloy base metal could be found at about 20mm from the weld interface. Regardless of the welding conditions, the joint efficiency in terms of tensile strength was 95–101% of that of the composite material base metal and the maximum elongation was 71% of that of the composite material base metal. Friction welded joints with good joint efficiency fractured near the weld interface of the heat affected zone of the composite base metal. The impact values of the welded joints with a notch in the weld interface were about 70% of those of the composite material base metal.

Keywords: Burn-off; Fracture; Friction welding; Metal matrix composites (MMC); Microstructure; Particle dispersion.

INTRODUCTION

The application of light metal materials is essential for constructions which are becoming more diversified in terms of weight, strength, and so on. However, when applying materials such as composites which are difficult to make into products of great length and are moreover of high cost, it is necessary to use them by welding to other metals. The authors have reported in past that, in friction welding aluminium alloy based composite materials,^[1,2] and composite material to its matrix alloy, it is possible to obtain sound joints when appropriate welding conditions are selected.^[3] Furthermore, they established that, at the weld interface between composite material and aluminium alloy, a recognisable phenomenon is that ceramic particles included in the composite material move to the other part, i.e. aluminium alloy.^[4]

In this study, the friction welding process was applied to welding of aluminium alloy matrix composite material and an aluminium alloy whose composition was different from that of the matrix alloy, and the microstructures and mechanical properties of the dissimilar joints obtained were investigated.

MATERIALS AND TESTING METHODS USED IN THE STUDY

Materials used in this study were 6061 aluminium alloy matrix composite material (19mm diameter, called MMC from now on) in which 20.5 vol% alumina particles were diffused, and 5052 aluminium alloy (BE-H14, 20mm diameter, called 5052 alloy from now on) which has a medium level of strength for an aluminium alloy and has been used fairly often as structural material. They were machined into test pieces of 19mm diameter and 80mm length, and faying surfaces were degreased immediately before friction welding was executed. The chemical composition and mechanical properties of the materials are shown in Table 1 and Table 2.

Friction welding was conducted by placing the MMC on the rotation side with the welding conditions shown in Table 3 and using a brake-type friction welding machine (Maximum 68 kN thrust). The joints obtained were subjected to microstructural examination, Vickers hardness testing, tensile testing using JIS 4 specimens with their weld interfaces at the centre of the gauge length, and Charpy testing using JIS 3 specimens with a notch at the interface, all carried out at room temperature.

TEST RESULTS AND DISCUSSION

Macroscopic Structures and Burn-off

An example of the macroscopic structure in an axial cross section of a weld joint is shown in Fig. 1. The weld interface can be identified distinctly as with MMC/6061 alloy joints,^[3] and the heat affected zone on the MMC side is noticeably concave-shaped whilst that on the 5052 alloy side can be observed to be parallel to the weld interface. The width of this heat affected zone tends to be greater on the 5052 alloy side.

In terms of appearance, whilst, in the MMC/6061 alloy joints,^[3] the 6061 alloy had a larger degree of flash than the MMC, in this study, the flash of the MMC was greater than that of the 5052 alloy because the MMC suffered a greater degree of deformation. Some joints showed recognisable cracks at the flash produced from the MMC as the friction welding time was set longer. However, no cracks were noticeable at the flash produced from the 5052 alloy regardless of welding conditions.

The result of measuring the burn-off (or total loss) is shown in Fig. 2. When the friction pressure is the same, the longer the friction time, the greater the total loss. When the friction time is the same, the total loss shows larger values

**Fig. 2** Relation between friction time and burn-off (or total loss)

with larger friction pressure, but its difference according to the level of friction pressure is small. As is clear from the macroscopic structure of Fig. 1, the deformation of the MMC is greater than that of the 5052 alloy and about 65% of the total loss was caused by deformation of the MMC. The values of total loss were approximately the same as those of MMC/6061 alloy joints,^[3] and the deformation on the MMC side was of approximately the same degree as that which occurred when the similar materials were friction welded.^[1]

Observation of Microscopic Structures

The structure of a joint obtained with $P_1 = 50$ MPa and $t_1 = 2$ sec is shown in Fig. 3 as an example of the microscopic structure of the axial cross section through the axial centre of the central part of a weld joint. The 5052 alloy side close to the weld interface showed similar features to those of aluminum alloy similar metal joints,^[5,6] that is, it displayed a region parallel to the weld interface with a lamellar fine microstructure, and a part adjacent to it where fibrous microstructure can be observed to have deformed in the direction of flash flow. The MMC side showed a similar structural change to that of the 5052 side, that is, alumina particles became slightly smaller in the area close to the weld interface, and some alumina particles were recognised to have moved to the 5052 side. This is presumably because, at the weld interface, since plastic flow occurs with mechanical mixing and flash extrusion,

Fig. 3 Microstructure of friction welded joint ($P_1 = 50$ MPa, $t_1 = 2$ sec)

alumina particles were crushed into finer ones and some, crossing the weld interface given the axial thrust, intruded into the 5052 side.

To examine the microscopic structures further in detail, an investigation was conducted using a scanning type electron microscope. An example of the results is shown in Fig. 4. At the central part of the joint, the microstructure did not look much different from the results of observation by the optical microscope, but there were many fine alumina particles found at the weld interface which had not been clearly recognisable with the optical microscope. In the region between the centre and the periphery of the joint, traces of mechanical mixing were apparent and alumina particles were noticeable in the mechanically mixed region on the 5052 alloy side. These alumina particles in the mechanically mixed region were finer than those in the base metal. Such mechanical mixing was recognised distinctly in dissimilar joints of aluminium alloys.^[7] However, it was not recognised in welding between materials such as the combination of pure aluminium and carbon steel^[8]

Fig. 4 SEM micrographs of friction welded joint ($P_1 = 60$ MPa, $t_1 = 2$ sec)

whose base metals have considerable difference from each other in high temperature deformation resistance. The MMC used in this test has a large number of high heat resistance alumina particles dispersed, but presumably the mechanical mixing was noticeable clearly because the matrix was aluminium alloy. At the flash of the 5052 alloy, there was a part to which the MMC was observed to have stuck. The thickness of this stuck MMC was as little as about 100/μm. These above-described changes in microstructure could be observed in all the joints regardless of welding conditions.

Hardness Profile of Joints

An example of a hardness profile at the central part of a joint through the axial centre is shown in Fig. 5. Hardnesses of the MMC side are measured on the matrix. The hardness distribution of the joint showed slightly higher values at the weld interface than in both base materials, and a softened area was noticeable on the 5052 alloy side. The hardness of this softened area recovered to the level of the base materials at about 20 mm from the interface. On the other hand, the hardness of the MMC side showed a slight variation owing to the influence of alumina particles, but there was no recognisable change such as a softened area. The emergence of a softened area on the 5052 alloy side is a phenomenon observable with joints in general for which base materials have been hardened through work hardening or heat treatment.^[5,6] Softened areas could be recognised in friction-welded joints of the 6061 alloy^[5] which is the matrix alloy of the MMC in this study, and of the MMC whose diffused particulate alumina content is smaller, i.e. 16 vol%.^[11] It is thought that a softened area did not exist in the MMC used in this study because it had a large volume of alumina particles, i.e. 20.5 vol%, diffused.

Results of Tensile Testing

Results of tensile testing of the friction-welded joints are shown in Fig. 6. The tensile strength of the joints hardly

Fig. 5 Hardness profile of friction welded joint ($P_1 = 60$ MPa, $t_1 = 2$ sec)

Fig. 6 Results of tensile testing

showed any difference with varying friction pressure. It showed a tendency to decrease slightly at 3 or 4 seconds of friction time, but the difference with friction time was so small that the tensile strength could be regarded as nearly the same. The tensile strength of the joints displayed a good result, that is, 95–101% of the MMC base material value. As for the fracture mode of the joints, some of the joints obtained with 50 MPa friction pressure and 2 or 3 seconds friction time were observed to include part of the weld interface in their fracture. With other conditions, fracture occurred at the heat affected zone of the MMC side adjacent to the weld interface as with MMC/6061 alloy joints.^[3] Elongation of joints increased with 50 MPa pressure, as the friction time increased, but with 60 MPa it showed a tendency to decrease, though slightly, when the friction time was increased. The reason why elongation decreased with the conditions of 50 MPa friction pressure and 2 or 3 seconds friction time is presumed to be that, with these conditions, like joints obtained with other welding conditions, some joints fractured at the heat affected zone of the MMC side and some joints fractured also at the weld interface, and, with joints which show these fracture modes, elongation became extremely small. However, the elongation of the joints which fractured at the heat affected zone was 6–8% and showed approximately the same level of values as that of the joints obtained with other welding conditions. Even with the joint which showed the highest elongation, it was reduced to about 71% that of the MMC base material.

Figure 7 shows an example of the fracture surfaces observed after the tensile test using a scanning electron microscope. The fracture surfaces of both base materials displayed dimples which represent ductile fracture. The dimples in the MMC were larger than those in the 5052 alloy and alumina particles were observable at the bottom of the dimples. The fracture surfaces of the joints which had fractured including the weld interface were brittle for both MMC and 5052 alloy sides. The one on the 5052 alloy side was more uneven than the one on the MMC side and had alumina particles observable in some areas.

Fig. 7 Microfractographs of tensile fracture surfaces of base metal and friction welded joints

In the joints which fractured at the heat affected zone of the MMC side, dimples of about the same size as those in the MMC base material could be observed in the entire fracture surface.

Results of Impact Testing

Results of impact testing are shown in Fig. 8. With 50 MPa friction pressure, the impact values of joints improved as the friction time became longer, whilst, with 60 MPa friction pressure, they fell as the friction time became longer. With MMC/6061 alloy joints,^[3] the impact values of the joints obtained were about the same as those of the MMC base material. In contrast, the joints obtained in this study showed lower impact values than the base materials. This is considered to be because, whilst, with the MMC/6061 alloy joints, the hardness of the notched weld interface showed lower hardness than the base materials despite having higher values than the softened area of the heat affected zone, the weld interface of joints in this test became harder than the base materials as shown in Fig. 5.

As an example of the result of observing fracture surfaces after impact testing using a scanning electron microscope, Fig. 9 shows the fracture surfaces of the base metal and the respective joints which showed the highest and the lowest impact values. The fracture surfaces of both MMC and 5052 alloy base metals display dimples all over. As

Fig. 8 Results of impact testing

Fig. 9 Microfractographs of impact fracture surfaces of base metal and friction welded joints

with the tensile fracture surfaces, more dimples on the MMC base metal were noticeably smaller than those on the 5052 alloy base metal, but the difference in the diameter of dimples between the base metals was smaller than with the tensile fracture surface. With the joint which showed the highest impact value, dimples could be seen on its entire fracture surface and alumina particles which acted as cores of dimples were clearly noticeable on the fracture surfaces of both base metals. The fracture surface of the joint which showed the lowest impact value was a brittle one although dimples were observable.

CONCLUSIONS

Combining the 5052 aluminium alloy and the 6061 aluminium alloy matrix composite material with 20.5 vol% alumina particles dispersed, friction welding was conducted with a variety of welding conditions. As a result of investigating the structure and mechanical properties of the joints obtained, the following conclusions were drawn:

1. At the weld interface of the joints, mechanical mixing was induced and caused alumina particles contained in the composite material to be finer and some of them to move to the 5052 alloy side.
2. The hardness of the weld interface of the joints showed slightly higher values than that of both base metals. The hardness of the MMC side hardly showed any recognisable change but, on the 5052 alloy side, a softened area was noticeable and the hardness recovered to the level of the base metal at a position about 20 mm from the weld interface.
3. The tensile strength of the joints showed nearly the same level of values regardless of welding conditions, that is, 95–101% that of the MMC base material, representing good results. The elongation of the joints showed reduced ductility values, i.e. about 71% that of the MMC base material. The fracture position of the joints which showed good values for both tensile strength and elongation was located at the heat affected zone close to the weld interface on the MMC side.
4. The impact value of the joints was reduced, to about 70% of that of the MMC base metal even with the joint which showed the highest value.

Grain Refinement and Strengthening of Aluminum Alloys: Cold Severe Plastic Deformation Model

Xiao Guang Qiao, Nong Gao, and Marco Starink

Materials Research Group, School of Engineering Sciences, University of Southampton, Southampton, SO171BJ, United Kingdom

Abstract

This paper presents a model which quantitatively predicts grain refinement and strength/hardness of Al alloys after very high levels of cold deformation through processes including cold rolling, equal channel angular pressing (ECAP), multiple forging (MF), accumulative rolling bonding (ARB) and embossing. The model deals with materials in which plastic deformation is exclusively due to dislocation movement, which is in good approximation the case for aluminium alloys. In the early stages of deformation, the generated dislocations are stored in grains and contribute to overall strength. With increase in strain, excess dislocations form and/or move to new cell walls/grain boundaries and grains are refined. We examine this model using both our own data as well as the data in the literature. It is shown that grain size and strength/hardness are predicted to a good accuracy.

Keywords: Al alloys; Grain refinement; Modelling; Severe plastic deformation; Strengthening.

INTRODUCTION

Deformation to effective strains higher than about 2 is achieved in a range of processes that are either industrially relevant presently or very promising in terms of future application. Established processes include cold rolling to high strains and embossing. In addition to these, the last three decades has seen extensive research in the field of newer processes collectively named severe plastic deformation (SPD) techniques.^[1,2,3] These techniques include equal channel angular pressing (ECAP), high pressure torsion (HPT) and accumulative rolling bonding (ARB). One of the main advantages of these SPD techniques is that ultra high plastic deformation (with strains in the order of 10 and higher) is achieved without a substantial change in dimensions of the worked sample, thus allowing very strong grain refinement, whilst avoiding contaminations that may be introduced in other techniques.^[1,3]

Alloys with fine grains have many attractive properties such as good formability and superplasticity, and their strength is increased. To exploit these benefits it is crucial to understand the mechanisms of grain refinement and to have the ability to accurately predict the grain size after these high deformation processes. Ultra fine grains or even nanostructured grains (grains with size below 100 nm) can generally only be obtained if the processing temperature is limited to avoid (dynamic or static) recrystallisation. There are a number of physical models that interpret the grain refinement mechanism during SPD. Conventional dislocation theory^[4,5,6,7] indicates that at the early stage of

deformation a very high dislocation density is introduced, which leads to the formation of an intragranular structure consisting of cells with thick cell walls and low angles of misorientation. As the strain increases, the thickness of the cell walls decreases. These walls evolve into grain boundaries, and ultimately an array of ultra fine grains with high-angle non-equilibrium grain boundaries (GBs)^[3,8] are formed. (Non-equilibrium grain boundaries may be present where there are non-geometrically necessary dislocations i.e. excess dislocations that do not contribute to the formation of misorientation at a grain boundary.) Xu et al^[9] and Langdon^[10] proposed a grain refinement model based on the shear band width and ECAP routes. These models describe possible mechanisms in a qualitative sense and do not predict the grain size in a quantitative way. Baik, Estrin and co-workers^[11] reported a dislocation density based predictive model of the grain refinement of pure Al during ECAP. The model can accurately fit the grain size of pure Al after different passes of ECAP, but to achieve this, a range of parameters need to be fitted.

An often claimed potential advantage of SPD is that the significant grain refinement would result in significant strengthening.^[2,3] However, it should also be considered that strengthening due to grain refinement is strongly material dependent: it is relatively low for Al alloys. Ashby,^[12] Nes and coworkers^[13,14,15,16,17] Hansen and coworkers^[18,19,20,21,22,23] and Estrin and co-workers^[11,24] developed a number of strengthening models incorporating work hardening contributions. Ashby^[12] proposed a model to predict dislocation generation due to

nonshearable particles. Nes^[13] studied the yield strength of conventionally deformed metallic materials during recovery through a strengthening model employing dislocation strengthening and grain boundary strengthening. Later, Nes, Marthinsen and co-workers^[14,15,16,17] further expanded this model and applied it to ultra fine-grained (UFG) Al alloys processed by SPD. Hansen and co-workers^[18,19,20,21,22,23] developed a strengthening model to study deformed metals, where the grain boundary strengthening follows the Hall-Petch^[25,26,27] relation and dislocations are considered to store in subgrain boundaries only. Estrin and co-workers^[11,24] constructed a dislocation based model in which dislocations storing in cell walls and grain interiors were considered to have the same strengthening effect. The Estrin et al^[11,24] model, in its original or slightly modified form, was extensively applied to predict strength of SPD processed alloys.^[28,29,30,31] Toth et al^[32] recently incorporated grain subdivision and geometrically necessary dislocations (GNDs) and further expanded this dislocation based model to predict texture, grain size, misorientation distribution and strain hardening of SPD processed alloys. These strengthening models either rely on experimental determination of several parameters (for instance, the dislocation density and the grain size in Hansen's model were obtained by EBSD measurements), or involve a number of fitted parameters (e.g. Estrin model).

The objective of the present study is to construct a model to predict the grain size and yield strength/hardness of a range of Al alloys subjected to high levels of cold plastic deformation. The model will include grain boundary strengthening, solid solution strengthening, precipitation strengthening and dislocation strengthening. Following earlier work from our group^[33] we will avoid considering width of cell walls and simplify the treatment of dislocations to consider only volume average dislocation densities. The aim is to provide a transparent, computationally friendly model, with very limited number of fitted parameters as compared to the above mentioned models and verify this model by comparison to data on alloys processed by SPD and by industrially relevant cold deformation processes.

THE MODEL

Dislocation Generations

In many metals and alloys cold plastic deformation takes place in most conditions mainly by dislocation movement. Although some deformation through twinning can occur, for example in magnesium, this only changes crystal direction to benefit the dislocation movement and does not contribute much to the overall deformation.^[34] The moving dislocations may be blocked by obstacles (such as other dislocations, particles and grain boundaries), or stored in grains; and new dislocations can be generated to

continue the deformation. This process was quantitatively studied by Kocks, Mecking and Estrin^[35,36,37,38] through an evolution equation (the KME model):

$$\frac{d\rho_{ig}}{d\varepsilon} = (bl)^{-1} - k_2\rho_{ig} \quad (1)$$

where ρ_{ig} is the (volume averaged) dislocation density (in the grains), ε is the strain, b is the Burgers vector, l is the mean free path for dislocation movement and k_2 is a constant. The $(bl)^{-1}$ term in Eq. 1 is associated with the athermal storage of dislocations due to moving dislocations blocked by obstacles.^[38] The $k_2\rho_{ig}$ term in Eq. 1 is related to the dislocation density decrease due to annihilation. We take this 'annihilation' to mean that dislocations are accumulated into grain boundaries (see "Formation of Cell Walls/Grain Boundaries" section and,^[33] they are effectively subsumed in the grain boundary). If the first term is dominant, the total dislocation density increases with strain as:

$$\rho_g = (bl)^{-1}\varepsilon \quad (2)$$

We will term ρ_g the total generated dislocation density, the volume averaged dislocation density that would be obtained if no dislocations are annihilated. Equation 2 can be alternatively obtained by Orowan equation.^[39] The volume averaged dislocation density that is stored in grains ρ_{ig} can be obtained by integrating Eq. 1:

$$\rho_{ig} = (blk_2)^{-1} - ((blk_2)^{-1} - \rho_0)e^{-k_2\varepsilon} \quad (3)$$

where ρ_0 is the initial dislocation density stored in grains.

We consider the strengthening contribution of dislocations follows the classical relation:^[40,41,42]

$$\Delta\tau = \alpha_1 Gb\sqrt{\rho_{ig}} \quad (4)$$

$\Delta\tau$ is the shear stress increment due to dislocation density increase, α_1 is a constant, value of which is about 0.3,^[41] G is the shear modulus. The relations of the shear strain and the shear stress and their equivalent counterparts of polycrystalline metals in plastic deformations are given by,^[43,44]

$$\frac{d\sigma}{d\tau} = \frac{d\gamma}{d\varepsilon} = M \quad (5)$$

M is the Taylor factor, γ , τ are the shear strain and the shear stress and ε and σ are the equivalent strain and stress. At the early stages of deformation, dislocation generation is dominant and generated dislocations are thought to store in grains. Thus, the evolution equation of flow stress increment with equivalent strain is provided by substituting Eq. 2 in to Eq. 4:

$$\Delta\sigma = \alpha_1 MG \sqrt{\frac{b}{1}} \sqrt{\varepsilon} = K_A \sqrt{\varepsilon} \quad (6)$$

Equation 6 holds when strain is between about 0.01 to 0.05 for a range of Al alloys as well as other alloys.^[12] We consider that dislocation generation during straining is continuous, and through extending application of Eq. 6 to large strain, the total volume averaged amount of dislocations generated per volume is provided by substituting Eq. 6 to Eq. 2:

$$\rho_g = \left(\frac{K_A}{\alpha_1 M G b} \right)^2 \epsilon \quad (7)$$

K_A can be obtained experimentally through tensile test or predicted using the model described in Ref. [33]. The latter model incorporates (amongst others) Eq. 4 to Eq. 7 and also considers the contribution of the solid solute atoms to the mean free path to provide:^[33]

$$K_A = C_2 G M^{3/2} b^{1/2} \left[\left(\frac{f}{2r} \right)^2 + \sum [B_i x_i]^2 \right]^{1/4} + K_A^0 \quad (8)$$

where C_2 and K_A^0 are constants, r and f are average radius and the average volume fraction of non-shearable particles, respectively. X_i are concentrations of alloying elements i and B_i are the constants related to the relevant elements. Detailed description of the model of total generated dislocations and K_A and identification of the values of the parameters is provided in Ref. [33].

2.2 Formation of Cell Walls/Grain Boundaries

Typically, the dislocation density in grains after cold deformation at large strain (about 4 to 10) is of the order of magnitude of 10^{14} m^{-2} in Al alloys,^[45,46,47,48,49,50] which is two orders of magnitude lower than the generated dislocation density predicted by Eq. 7. In the KME model, the second term in the right part of Eq. 1 accounts for the difference between total generated dislocation density and dislocation density in grains. The physical essence behind this difference has been attributed to the annihilation due to recovery, but it is not clearly defined how the excess dislocations annihilate and recover.^[38]

We believe that annihilation of dislocations of opposite signs on the same slip plane is unlikely^[33] (an exception is that it occurs when the reverse strain involved,^[51] but it is not the topic of the current work). Part of the dislocations generated during deformation store in grains (for instance due to being trapped by obstacles, including second phase particles and other dislocations) and the excess dislocations either form new cell walls or move to cell walls/grain boundaries. On increasing deformation, dislocations are continuously generated, and accumulate at/in the cell wall/grain boundary. During this process cell walls gradually transform into grain boundaries. Therefore, the length of the totally generated dislocations (L_g) is equal to the length of dislocations in grains (L_{ig})

plus the length of dislocations that have either formed or are accumulated in grain boundaries (L_{GB}), i.e.

$$L_g = L_{GB} + L_{ig} \quad (9)$$

The length of dislocations stored in tilt low angle grain boundaries (L_{tilt}) is related to the misorientation angle between the adjacent grains (θ) through the basic equation $\theta = b/s$ ^[52] in which s is the average distance between dislocations, i.e.:

$$L_{tilt} = \frac{\theta}{b} A = \frac{\theta}{b} S_v^{tilt} V \quad (10)$$

where A is boundary area, V is entire volume of the material and S_v^{tilt} is boundary area per unit volume for subgrains (cells) with tilt boundaries. Equation 10 is valid for a tilt subgrain boundary. For a mixed tilt/twist subgrain boundary, the equation can be approximately written as,^[18,19]

$$\rho_{cw} = \frac{L_{cw}}{V} = 1.5 \frac{\theta}{b} S_v^{cw} \quad (11)$$

where L_{cw} and ρ_{cw} are dislocation length and dislocation density stored in subgrain boundaries (cell walls), respectively. S_v^{cw} is boundary area per unit volume for subgrains (cells). The redundant dislocations in boundaries which do not contribute to the misorientation are neglected since the redundant dislocation number significantly decreases with increasing strain.^[18,19] In the present work we will consider that the latter equation also holds at least in good approximation for high angle grain boundaries (HAGBs),^[33] with the dislocation density now referring to the dislocations subsumed into the grain boundary. (We will discuss this point further in “Structure of LAGBs and HAGBs and Dislocation Densities” section.) Thus the density of dislocations forming/moving to cell walls/grain boundaries is taken as:

$$\frac{L_{GB}}{V} = \frac{L_g - L_{ig}}{V} = \rho_g - \rho_{ig} = \int 1.5 \frac{\theta}{b} dS_{ve} \approx 1.5 \frac{\bar{\theta}}{b} S_{ve} \quad (12)$$

where $\bar{\theta}$ is average grain boundary misorientation angle and S_{ve} is the equivalent boundary area per unit volume for refined grains formed in the deformation processing. The maximum possible value of $\bar{\theta}$ is 45° when the grains are randomly oriented.^[53] The value $\bar{\theta}$ for SPD processed Al alloys starts to approach a constant value (about 20 to 25°) after a certain strain (typically 3).^[33] Analysis of $\bar{\theta}$ data on a number of severely plastically deformed Al alloys^[22,46,54,55,56] has shown that $\bar{\theta}$ can be approximated well by.^[51,57]

$$\frac{\bar{\theta}}{\theta_m} = 1 - ((k\epsilon)^n / \eta + 1)^{-n} \quad (13)$$

where $n = 1$, and $\bar{\theta}_m$ is the maximum value that the average misorientation angle can take (45°)^[53]. A detailed explanation is provided in Ref. [51]. Here, to simplify the equation, we take $k = 1$ and fit the on θ for a range of alloys to obtain $\eta = 0.3$.

The boundary area per unit volume, S_v , is in practice often obtained by measuring the mean lineal intercept length, $\bar{L}$, via the fundamental relationship $S_v = 2/\bar{L}$ ^[58,59]. The grain shapes are thought to resemble that following a Poisson-Voronoi tessellation^[60,61,62] (see also,^[63,64] and thus S_{ve} relates to the grain size as:^[60]

$$S_{ve} = S_v - S_{v0} = 2.91/d_e \quad (14)$$

where S_{v0} is initial boundary area per unit volume prior to deformations, d_e is defined as the equivalent refined grain size for a material with very large starting grain size ($d_0 \gg d_e$). Substitution of Eq. 14 to Eq. 12 provides,

$$d_e = 4.365 \frac{\bar{\theta}}{b} \frac{V}{L_{GB}} \quad (15)$$

Thus, the equivalent refined grain size (d_e) of a material after a given strain can be calculated through substituting Eqs. 3, 7, 12 and Eq. 13 to Eq. 15. (The latter equation for d_e is equivalent to the one provided in Ref. [33]). We have here derived this equation in a different way incorporating dislocation line lengths, which we believe to be clearer, and we have modified the model to incorporate dislocations in the grain.) From the above follows that the average grain size (d) after deformation is obtained through from the original grain size (d_0) and d_e as follows:

$$\frac{1}{d} = \frac{1}{d_0} + \frac{1}{d_e} \quad (16)$$

In most cases d_0 will be substantially larger than d_e , and the size of coarse grains in the as received condition does not influence the grain size after deformation.

Hardness/Yield Strength of Deformed Al Alloys

In the present model, the yield strength of SPD processed Al alloys is taken as a superposition of grain boundary strengthening ($\Delta\sigma_{gb}$) and critical resolved shear stress (CRSS) increments caused by the intrinsic stress (τ_0), solid solute elements ($\Delta\tau_{sol}$), precipitates ($\Delta\tau_{ppt}$) and dislocations ($\Delta\tau_d$). It has been shown^[54,65,66,67] that an effective way of approximating this superposition is through:

$$\sigma_y = \Delta\sigma_{gb} + M(\tau_0 + \Delta\tau_{sol} + \Delta\tau_{ppt} + \Delta\tau_d) \quad (17)$$

If no substantial ageing or precipitation occurs, $\Delta\tau_{sol}$ and $\Delta\tau_{ppt}$ are constant, and we can introduce $\sigma_0 = M(\tau_0 +$

$\Delta\tau_{sol} + \Delta\tau_{ppt})$, which has a constant value and depends only on alloys. Equation 17 can then be simplified to:

$$\sigma_y = \sigma_0 + \Delta\sigma_{gb} + M\Delta\tau_d \quad (18)$$

In alloys that are not precipitation hardened σ_0 can be taken as the yield strength of the alloy in fully annealed condition. Grain boundary strengthening ($\Delta\sigma_{gb}$) may be expressed as:^[14,68]

$$\Delta\sigma_{gb} = \alpha_2 Gb \left(\frac{1}{d} \right) \quad (19)$$

where α_2 is a constant, d is the grain size predicted by Eq. 16. (For the present alloys both the Hall-Petch relation and the latter equation predict strengthening that is very limited as compared to other contributions.^[51] This will be further discussed in “Grain Boundary Strengthening” section.) The dislocation strengthening ($\Delta\tau_d$) is calculated by Eq. 4.

The Vickers hardness is expressed as:^[69]

$$Hv = C\sigma_y \quad (20)$$

where C is a constant, the value of which ranges from 3.05 to 3.28 for worked Al-1050 by conventional mechanical processing (when $Hv > 30$ HV).^[54] Here, C is taken as the average over that range, i.e. $C = 3.16$ (For further analysis on the ratio of hardness to yield stress of metallic alloys, see Ref. [69]).

MATERIALS AND EXPERIMENTAL PROCEDURE

The present study was in part carried out using data from the literature and in part on original data. The latter data was obtained from studies on Al-1050, Al-Zr and Al-Zr-Si-Fe alloys. Al-1050 is commercial purity aluminium and was supplied as an extruded rod of 9.53 mm diameter. AlZr and AlZrSiFe were supplied as plate with thickness of 12 mm and width of 60 mm, in as cast condition. The average grain sizes of these three Al alloys in as received condition is 45 μm , 690 μm and 540 μm respectively. The chemical compositions are shown in Table 1. The compositions are actual compositions obtained by chemical analysis.

The alloys were cut to rods of 65 mm in length and 9.53 mm in diameter, then processed by equal channel angular pressing (ECAP) up to 12 passes by route B_c at room temperature. The route B_c represents that the billet is rotated 90° in the same direction between each pass. For ECAP processing, the lubricated billet using a suspension of MoS_2 in mineral oil was pressed through a die containing two channels, equal in cross-section (9.7 mm diameter), intersecting at an angle $\Phi = 90^\circ$. The equivalent strain after one pass of ECAP is about 0.92.^[70] (Further details of the experimental set up were provided in Ref. [33, 54].)

Table 1 Composition of the aluminium alloys used in this study

Component	Al Wt. %	Cu	Fe	Mg	Mn	Si	Ti	Zr	Zn	Other, each
Al-1050	99.65	0.01	0.18	0.01	< 0.01	0.12	0.02	-	< 0.01	< 0.01
AlZr	Bal	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	< 0.01	0.15	< 0.01	< 0.01
AlZrSiFe	Bal	< 0.01	0.19	< 0.01	< 0.01	0.17	< 0.01	0.16	0.01	< 0.01

Electron backscattered diffraction (EBSD) was used to characterize the microstructure of the ECAP processed Al-1050, AlZr and AlZrSiFe Al alloys. Samples of 10 mm length used for EBSD analysis were machined from the centre of ECAP-processed billets. The surface of cross section was first mechanically ground up to 4000-grit SiC paper, then electropolished employing an electrolyte composed of 33 vol% nitric acid and 67 vol% methanol. The electropolishing was carried out with a DC voltage of 20–30 V for 30 seconds at -30°C . The equipment used was a JEOL JSM6500F thermal field emission gun scanning electron microscope (FEG-SEM) equipped with an HKL EBSD detector and HKL Channel 5 software. The SEM accelerating voltage was set to 15 kV. Step size is reported with the results; in most cases it was between 0.1 and $0.5\text{ }\mu\text{m}$. Orientation imaging microscopy (OIM) maps were obtained from the cross section perpendicular to the longitudinal direction of ECAP processed billets. The grain size was determined by an intercept method through an automated procedure. For misorientation angle distributions the lowest cut off angle was set at 2° .

Transmission electron microscopy (TEM) was conducted on the ECAP processed AlZr alloy using a JEOL 3010 microscope operating at 300 kV. Disks of 2 mm in thickness were cut from ECAP processed billets and ground to a thickness of 0.5 mm. Subsequently, disks of 3mm in diameter were punched out, followed by twin jet polishing by an electrolyte composed of 33% nitric acid and 67% methanol at a temperature of -30°C .

Throughout this paper we will report average grain sizes, d , as $1.455 \times \bar{L}$, where $\bar{L}$ is the average intercept length (i.e. assuming that grain shape approximates those obtained by a Poisson-Voronoi construction^[60]).

Microhardness was tested using an MHT-1 model micro Vickers hardness tester. Five hardness values were measured on the cross section at the centre area of the ECAP processed billets. A force of 300g was applied and held for 15 second.

EXPERIMENTAL RESULTS

EBSD

Microstructures of the Al-1050, AlZr and AlZrSiFe alloys processed by ECAP, as characterized by EBSD, are shown in Figs. 1–3, respectively. In these figures, the grey fine lines

represent grain boundaries of which the misorientation angle is between 2° and 15° . Dark lines are grain boundaries with misorientation angle greater than 15° . Misorientations less than 2° were ignored in order to remove the noise. The microstructure evolution of three alloys follows similar trends, i.e. after one pass of ECAP there is a strong increase in the amount of low angle grain boundaries; and with the increasing passes the fraction of high angle grain boundaries increases and the grain size decreases. The grain size of three alloys after various passes of ECAP is presented in Table 2 where grain boundaries are defined by misorientation angles greater than 2° , and grain size was obtained by measuring the mean intercept length and converting to an average grain size.

TEM and Microhardness

Figure 4 shows TEM micrographs of the AlZr alloy after 1, 4 and 8 passes of ECAP. The shape of grains is found to develop from an elongated shape after 1 pass into an equiaxed shape, and the size of the grains decreases with increasing number of passes (i.e. with increasing accumulated plastic strain). After one single pass of ECAP, the microstructure consists of an array of band-shaped subgrains (Fig. 4a). The spacing between each band is approximately $0.6\text{ }\mu\text{m}$. After 4 passes of ECAP, the band-shaped subgrains are replaced by equiaxed grains with intercept lengths of about $0.5\text{ }\mu\text{m}$ (Fig. 4c) and after 8 passes of ECAP the intercept length is further refined to $0.4\text{ }\mu\text{m}$ (Fig. 4e). As pointed out in previous work,^[33] the grain size measured by TEM is slightly smaller than that measured by EBSD (see Table 2) which is due to the high resolution and omission of grain boundaries with misorientation angle smaller than 2° in the EBSD measurement. (For comparison with model predictions, the grain size measured by EBSD is used, as this measurement contains more grains, is statistically better defined and appears to be less susceptible to measurement errors.). Two forms of dislocation aggregates in grain boundaries were observed. One form is a parallel dislocation array (Fig. 4f) and the dislocation spacing in the parallel dislocation array is very small. The other is a polygonized dislocation wall (Fig. 4f), similar to those in conventionally deformed metals during recovery.^[71,72] This indicates the parallel dislocation wall is the transition state between the polygonized dislocation wall and the formation of a grain boundary. In general, dislocation density is inhomogeneous.

Fig. 1 Microstructure of Al-1050 from EBSD (a) in the as-received condition and processed by ECAP for (b) 1, (c) 2, (d) 4, (e) 8 and (f) 12 passes

Fig. 2 Microstructure of AlZr alloys processed by ECAP for (a) 1, (b) 2, (c) 4 and (d) 8 passes

Fig. 3 Microstructure of AlZrSiFe alloys processed by ECAP for (a) 1, (b) 2, (c) 4 and (d) 8 passes

Table 2 Average grain size, d , of Al-1050, AlZr and AlZrSiFe after various passes of ECAP

Alloys	Pass number				
	1	2	4	8	12
Al-1050	2.87 μm	1.78 μm	1.47 μm	0.56 μm	0.54 μm
AlZr	3.03 μm	2.53 μm	1.89 μm	1.18 μm	
AlZrSiFe	2.87 μm	1.71 μm	1.63 μm	1.16 μm	

The Vickers hardness of three alloys after different passes of ECAP is shown in Table 3. For all three alloys, the hardness increases significantly during the first pass of ECAP and increases more gradually in the subsequent passes.

MODEL PREDICTIONS

Predicting the Grain Size and the Microhardness of Three Alloys

The grain size of Al-1050, AlZr and AlZrSiFe after various passes of ECAP is predicted using the present model. The values of parameters used in the model are provided in Table 4. Most of the parameters (incl. α_1 , α_2 , b , G and M) are known at least to a good approximation and their values are taken from the literature.^[12,68,74,75] The parameter determining the relation between $\bar{\theta}$ and accumulated effective strain (Eq. 13) is determined by fitting to literature data,

which provides $\eta = 0.3$. The value of K_A is calculated by Eq. 8. (In Ref. [33] K_A predictions are verified by comparison with tensile test data.) The initial dislocation density (ρ_0), has very little influence on predictions, and is taken as $1 \times 10^{13} \text{ m}^{-2}$, which is a typical value for annealed Al.^[73] σ_0 is taken as the yield strength of the alloy in the annealed condition, which equals 28 MPa for Al-1050,^[76] 14 MPa for AlZr and 50 MPa for AlZrSiFe. The last two values were obtained from hardness measurements, which were converted to yield strength using Eq. 20. k_2 and l are the only two parameters that are not determined from prior published data. In the present model, to determine these two parameters, we fit the model to hardness data of AlZrSiFe and calculate the root mean square error (RMSE) of the predicted hardness when tuning these two parameters. The best fitting, when RMSE reaches the minimum value, provides $k_2 = 1.86$ and $l = 5.6 \mu\text{m}$. k_2 is fixed throughout the present paper, i.e. it is applied to all alloys considered. The latter value of l is fixed for all commercial purity alloys with Al content higher than 99.5%.

The predicted grain sizes of the three alloys are presented in Fig. 5. The grain size here is an average value for all grains with all misorientation angles larger than 2° . (As mentioned above the grain size is defined as 1.455 times the mean intercept length.^[33] The predicted grain size fits the measured grain size to within an average deviation of 24%. A simplified variant of this model for grain refinement (in which ρ_{ig} is neglected) has been tested against a wide range of other Al alloys, such as Al-Mg, Al-Cu, Al-7075 and Al-6082, with similar average deviations.^[33]

Fig. 4 TEM micrographs showing the structural evolution of AlZr alloy after (a) 1, (b) 4, (c), (d), (e) and (f) 8 passes of ECAP, (d) dark field image of a grain pointed by an arrow in (c), (e) bright field image of a grain, (f) boundary structure of the grain in (e)

The predicted microhardness of the three alloys is shown in Fig. 6. The predicted hardness agrees very well with the experimental data.

Cold Rolled Al-1200

Liu et al^[22] reported data on the microstructure and the yield strength of cold rolled Al-1200 with thickness reduction from 40% to 99% (corresponding to true strains ranging from 0.5 to 5). In Figs. 7 and 8, their measured data is compared with predictions by the present model. (The experimental grain size data in Fig. 7 are measured from the TEM figures in Ref. [22]) In the TEM figures,^[22] the grains are not equiaxed, and instead approach a rectangularoid-shape. We thus approximate their size as

Table 3 Microhardness of Al-1050, AlZr and AlZrSiFe after various passes of ECAP

Alloys	Pass number					
	0	1	2	4	8	12
Al-1050	21.2 Hv	43.7 Hv	44.9 Hv	48.0 Hv	50.4 Hv	50.4 Hv
AlZr	18.7 Hv	39.2 Hv	39.9 Hv	41.3 Hv	41.1 Hv	
AlZrSiFe	29.6 Hv	50.7 Hv	53.6 Hv	57.5 Hv	61.2 Hv	

$d_{bw} \times d_{bw} \times \lambda_d d_{bw}$, where d_{bw} is the width of the bands, λ_d is the ratio of band length and width. Thus, Eqs. 14 and 15 can be modified as:

$$S_{ve} = \sqrt[3]{\lambda_d (2 + 1/\lambda)} / d_e \quad (21)$$

Fig. 5 Measured and predicted grain sizes of Al-1050, AlZr and AlZrSiFe after different passes of ECAP at room temperature. The grain size was measured using FEG-SEM equipped with EBSD

Fig. 6 Measured and predicted microhardness of ECAP processed Al-1050, AlZr and AlZrSiFe. The error bars represent standard deviation of five measurements

$$d_e = \sqrt[3]{\lambda_d d_{bw}} \quad (22)$$

$$d_e = 1.5 \frac{\bar{\theta}}{b} \frac{V}{L_{GB}} \sqrt[3]{\lambda_d} \left(2 + \frac{1}{\lambda_d} \right) \quad (23)$$

In the model, λ_d is measured in the TEM figures^[22] as 3, K_A is calculated to be 300 MPa,^[33] and σ_0 is taken as the yield strength in the annealed condition (19.3 MPa.^[77] The remaining parameters are taken as the same values as Al-1050, see Table 4 for details. The l is determined as 4.5 μm by fitting. The value of l is slightly smaller than that of Al-1050 because there are more alloying elements in Al-1200 and they form more particles. The predicted grain size and yield strength fit the measured data well and the RMSE are 0.33 μm and 2.9 MPa, respectively. Fig. 8 also presents the grain boundary strengthening

Fig. 7 Prediction of grain size of cold rolled Al-1200 as a function of the rolling strain. The experimental data are from Ref. [22]

Fig. 8 Prediction of yield strength of Al-1200 after different strain of cold rolling. The experimental data are from Ref. [22]

and the dislocation strengthening predicted by the model. Strengthening contribution of grain boundaries by Hall-Petch equation is plotted in Fig. 8 for comparison purpose. Hall-Petch constant is taken as 16 MPa $\mu\text{m}^{-1/2}$.^[27] The predictions indicate dislocation strengthening is the dominant strengthening mechanism.

Al-6061 Cold Deformed by ECAP, Multiple Forging, Rolling and ARB

Cherukuri et al.^[91] reported the microhardness of Al-6061 cold deformed by ECAP, multiple forging and ARB up to an equivalent strain of 5. This experimental data is plotted in Fig. 9, and in the same figure the hardness predicted by the present model is shown. For these predictions K_A is calculated to be 335 MPa (using the model in Ref. [33]), σ_0 is taken as is the yield strength in the annealed condition (105 MPa,^[78] The remaining parameters are taken as the same values as Al-1050, see Table 4 for details. The

only parameter that needed to be fitted is l , which is determined as 3.9 μm . The value of l is slightly smaller than that of Al-1050 and Al-1200, and this difference is thought to be caused by the fact that Al-6061 has more alloying elements. The predicted microhardness fits the measured data excellently for Al-6061 processed by ECAP and multiple forging, but the hardness of samples processed by ARB exceeds these predictions, i.e. for the same equivalent strain ARB processed Al-6061 achieves a higher hardness than Al-6061 processed by ECAP and multiple forging.

The reason for this discrepancy is thought to lie in the oxide layers and particles that are known to be introduced at the location of the bonds between the layers during ARB.^[78] This will influence the hardness in two ways. Firstly, the oxide particles will cause a local increase in K_A and thus cause an enhanced grain refinement. Experimental evidence for this has been provided by Lee et al.^[78] who observed through TEM that the bonding area of ARB processed Al-6061 possessed a grain size that is much smaller than that away from the bonding zone. That work also confirmed the presence of a large amount of fine oxide particles observed in the bonding zone. These findings are fully

consistent with our model, which indicates that the grain refinement is due to enhanced local dislocation generation around the non-shearable hard oxide particles. This grain refinement and additional dislocation generation is one reason for the enhanced hardness. A second reason for the enhanced hardness lies in the fact that the ARB processed material effectively has become an Al6061-Al₂O₃ (laminar) metal matrix composite (see TEM figures in Ref. [78]) which has a higher flow strength than the Al6061 alloy. In a further paper^[79] we will show that the present model can be expanded to incorporate the additional dislocation generation and grain refinement caused by the oxide particles, and that this expanded model can predict the hardness and grain size of the ARB processed alloy.

DISCUSSION

The present model brings together several elements and approaches to provide a new integrated model for prediction of grain size and strength/hardness of Al alloys subjected to severe cold deformation. The approaches taken

Fig. 9 Prediction of microhardness of Al-6061 processed by ARB, ECAP, multi-axial compression/forgings (MAC/F) and MAC/F+cold rolling. The measured Vicker's microhardness is taken from Ref. [91], the arrows shown in the figure are data points of ARB. Strengthening contribution of grain boundaries by Hall-Petch equation is plotted for comparison purpose. Hall-Petch constant is taken as $16 \text{ MPa } \mu\text{m}^{-1/2}$ [27]

in the present model are thought to be reasonable as well as computationally efficient (and ultimately successful, see below) but it should be clearly stated that for most elements incorporated in the present integrated model alternative approaches exist. Discussing all the possible alternatives for sub-models is not realistically possible, and we will here focus on the most pertinent issues and refer to other works for further discussion and comparison.

Model Accuracy and Validity of Model Parameters

The present model accurately predicts the grain size and yield stress/hardness of a range of Al alloys after different deformation process (see Figs. 10 and 11, data of embossed Al-1050 is from Ref. [80]). The grain size prediction is shown to be valid for a range of alloys. The root mean square error (RMSE) for hardness prediction is 1.7 HV, and the average accuracy of grain size prediction is 25%. In the model, the mean free path, l , is the only parameter which is fitted using the experimental data. The value of l should be dependent on alloying, decreasing with increasing content of alloying/impurity elements due to increasing amount of second phase particles and precipitates in the alloys. The determined values of l for different Al alloys presented in Table 4 do indeed show this dependency, decreasing from $5.6 \mu\text{m}$ for Al-1050 (Al-0.2%Si-0.2%Fe) to $3.9 \mu\text{m}$ for Al-6061 (Al-0.9%Mg-0.7%Si-0.2%Cu-0.2Fe). A key advantage of the present model is thus that the grain size and strength of an Al alloy can be predicted after a

Fig. 10 Measured and predicted of grain size of a number of Al alloys processed by various deformation techniques. Data of Al-1050 ECAP+Embossing is from Ref. [80]

Fig. 11 Measured and predicted of hardness of a number of Al alloys processed by various deformation techniques. Data of Al-1050 ECAP+Embossing is from Ref. [80]

given strain provided one parameter, l , is obtained either experimentally, or estimated from data provided here.

The concentration of alloying elements influences model predictions in several ways. Firstly, the composition influences K_A (see Ref. [33] for details), i.e. it influences rate of dislocation generation. Secondly, compositions influence strengthening contributions through solid solution strengthening and second phase particles. In the present paper we simplified the approach by making the approximation that the size, volume fraction and distribution of the second phase particles does not change significantly during cold deformation, therefore the solid solution strengthening, precipitation

strengthening and intrinsic strengthening are taken as a constant term σ_0 , the value of which is assumed unchanged by deformation. This assumption is valid for alloys with a small amount of particles or particles that are already small before deformation. To improve this aspect of the model further one would need to derive a predictive model for particle fracture and refinement during deformation.

Structure of LAGBs and HAGBs and Dislocation Densities

Prediction of grain size using the present model strongly relies on the relation of the average boundary area and the density of dislocations forming or joining the boundaries (see Eq. 10). Equation 10 was originally applied to low angle tilt boundaries formed by edge dislocations and its application is here extended to high angle grain boundaries (HAGBs) (see also Ref. [33]). This approach effectively assumes that when a cell wall transforms to grain boundary, the effective total amounts of dislocations needed to obtain a certain misorientation between neighboring grains is unchanged. The misorientation angle between two adjacent grains separated by a HAGB then increases further as moving dislocations reach this HAGB and are subsumed in it. Some of the boundary structures that occur in the transition from cell walls and low angle grain boundaries (LAGBs) to HAGBs have been observed in the present TEM work (see Fig. 4e and f).

Similar TEM results of the boundary structure evolution have been reported by Chang et al.^[72] Chang et al.^[72] observed that “on increasing strain, polygonized dislocation walls transform firstly into partially transformed boundaries, then into grain boundaries”,^[72] which is consistent with our model and the present EBSD results (see Figs. 1–3) which show that the fraction of LAGBs decreases with increasing strain.

Figure 12 shows the predicted evolution of average dislocation density, ρ_{ig} , for the alloys considered in the present work, together with data on dislocation densities for selected Al alloys obtained from the literature.^[49,50,81,82] Figure 12 shows that the model predictions broadly correspond with XRD determination of dislocation densities in most of the corresponding alloys. However, it is obvious that there are some deviations, and we believe that these deviations are mostly due to the following. Firstly it should be noted that XRD determinations of dislocation densities derive from measurement of micro strain from line broadening analysis.^[83] These methods cannot reliably analyze dislocation densities that are highly inhomogeneous. In particular, when a small volume fraction of material has a much higher dislocation density as compared to the majority of the material, then the XRD line broadening analysis will not be sensitive to the high dislocation densities areas. Secondly, TEM determinations of dislocation densities (open symbols in Fig. 12) tend to provide lower dislocation densities due to these measurements generally focusing on

Fig. 12 Prediction of densities of dislocations generated (DG) during deformations and dislocations stored in grains (IG). Experimental data for pure Al (ECAP, XRD), Al-1050 (rolling, EBSD), Al-1100 (ARB, TEM), Al-6082 (ECAP, XRD) and Al-Mg (ECAP, XRD) are from Refs. [50,81,82,49 and 50], respectively

lower dislocation density areas, whilst also possible loss of dislocations in the sample preparation can play a role. One effect here is that in TEM sample preparation local stresses are reduced and dislocations (especially geometrically necessary dislocations) are lost. In addition, there is some uncertainty on the reliability of determination of dislocation density through EBSD. Clearly these issues related to accuracy of various dislocation density measurements need to be studied in more detail. However, when we take these points into account, Fig. 12 shows that the dislocation densities predicted by the present model are broadly in line with measured data on similar alloys, and the model broadly captures the correct trends on increasing strain.

Grain Boundary Misorientations

The relation between dislocation density in a cell wall or low angle grain boundary and the misorientation between the grains adopted in the present work (Eq. 10), was originally provided in the context of boundaries/cell walls with low misorientation angles.^[18,20] As average misorientation angles increase to the typical values observed after SPD of about 30° we may expect that deviations will be introduced. To estimate the magnitude of possible deviations we can compare the expressions for misorientation angles for the case of dislocation that are parallel to grain boundaries. In this case the low angle approximation is:^[84]

$$\frac{b}{s} \cong \theta \quad (24)$$

where s is the average distance between dislocations. The linear relation between θ and $1/s$ is analogous to Eq. 10. For higher angle misorientation several relations have been suggested:^[85,86]

$$\frac{b}{s} = 2 \sin\left(\frac{\theta}{2}\right) \quad (25)$$

or^[87]

$$\frac{b}{s} = 2 \tan\left(\frac{\theta}{2}\right) \quad (26)$$

or^[88]

$$\frac{b}{s} = \tan \theta \quad (27)$$

The differences in the expressions are due primarily to different assumptions on the arrangement of dislocations in the grain boundary. A conclusive analysis as to which of these expressions (Eqs. 25–27) is more accurate is not available.

If we calculate the deviations introduced by the various approximations for a typical θ of about 30° we find deviations of 1%, –2% and 10% between Eq. 24 on the one hand and Eqs. 25, 26 and 27, respectively. Thus we can

expect that the adoption of the linear relation between total amount of dislocations subsumed in the grain boundary and θ our model has an uncertainty in prediction of grain size of about 2%, increasing to 10% if Eq. 27 would be the correct approximation. Such deviations are relatively limited (they are within the 25% accuracy in grain size predictions shown in “Model Accuracy and Validity of Model Parameters” section) and would not significantly influence analysis and conclusions presented here.

Grain Boundary Strengthening

In the present work we used the grain size strengthening equation (Eq. 19) from work by Nes and co-workers.^[14,68] This approach provides a grain size strengthening that is somewhat different from the classical Hall-Petch (see e.g. Refs. [25,26,27]) approach, which is regularly invoked in a range of publications. Several possible explanations for the $d^{-1/2}$ dependency of grain size appearing in the Hall-Petch approach have been proposed (see e.g. Refs. [89,90]). To consider the possible influence of the Hall-Petch approach on model predictions we provide the following assessment.

The most complete set of data for grain size dependency of flow stress for an alloy that is similar to the alloys considered in “Predicting the Grain Size and the Microhardness of Three Alloys”, “Cold Rolled Al-1200”, “Al-6061 Cold Deformed by ECAP, Multiple Forging, Rolling and ARB” sections is that for the Al-1050 alloy provided by Hansen.^[27] Hansen’s data^[27] indicates a Hall-Petch constant of 25 MPa· $\mu\text{m}^{1/2}$ for strain ~0.2% and 7 MPa· $\mu\text{m}^{1/2}$ for strain 7%, with the latter strain value being a typical average strain achieved in hardness tests. Using the average on this strain range (16 MPa· $\mu\text{m}^{1/2}$) one would obtain an increase in yield strength of up to about 22 MPa and an increase in hardness of about 7 HV for the smallest grain sizes considered in the present work (0.5 μm). This grain size hardening is comparable to the hardening calculated using Eq. 19, thus adopting the Hall-Petch empirical equation would cause little difference. In Figs. 8 and 9 we have added the Hall-Petch type predictions, confirming differences are small.

There will be some difference due to the Hall-Petch relation containing a $d^{-1/2}$ dependency whilst Eq. 19 has a d^{-1} dependency. However, possible uncertainties introduced are thought to be limited in comparison to the overall hardening, and hence in the context of the present model and data further discussion is not fruitful. (It is also noted that for high purity Al (>99.99%) Hall-Petch constants can be 40 to 50 MPa $\mu\text{m}^{1/2}$.^[27] This increased Hall-Petch constant would increase the grain size strengthening effect.)

CONCLUSION

A computationally efficient model that accurately predicts the grain size and hardness of a range of Al alloys

processed by cold deformation at very high strains including cold SPD is presented. Conclusions are drawn as follows:

1. The model uses very few fittable parameters, only mean free path, l , is fitted.
2. Parameters input in the model include the composition of an Al alloys, size of non-shearable particles and strain.
3. The model is tested using the published data of a number of Al alloys processed by ECAP, cold rolling, forging and ARB. The accuracy of the prediction is good.
4. The model is applicable to the homogenous deformation of Al alloys with short and fine particles. It can be easily extended to the precipitation strengthening Al alloys with proper modifications.

Grain Refinement of Cast Aluminum by Heterogeneous Nucleation Sites

Yoshimi Watanabe and Hisashi Sato

Department of Physical Science and Engineering, Nagoya Institute of Technology,
Gokiso-cho, Showa-ku, Nagoya, 466-8555, Japan

Abstract

Grain refinement plays a vital role in cast and wrought Al alloys. To achieve a grain refined cast microstructure, addition of Al-Ti, Al-Ti-B, and Al-Ti-C refiners has become a common industrial practice. The refiners introduce a large number of particles such as Al_3Ti , TiB_2 , or TiC into the Al melt, and these particles act as heterogeneous nucleation sites for α -Al grains. In this article, some of the main theories of grain refining by refiners, and the crystal structure and shape of Al_3Ti in Al-Ti refiner are briefly summarized to outline the physical aspects of grain refinement. Then, our results on grain refining performance of pure Al casts by equal-channel angular-pressed Al-11vol% Al_3Ti refiner, cold-rolled Al-11vol% Al_3Ti refiner, Al-10vol%Ti refiner, and Al-10vol% L1_2 -type $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ refiner will be described. Fragmentation behavior of Al_3Ti platelets in Al-Ti refiner by friction stir processing is also presented.

Keywords: Al_3Ti ; Cast; Cold rolling; Disregistry; Equal-channel angular pressing (ECAP); Friction stir processing (FSP); Grain refinement; Hermans orientation parameter; Heterogeneous nucleation; L1_2 -type $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$.

INTRODUCTION

Grain refinement of α -Al grains is important for improving the strength of as-cast Al, since as-cast Al has a columnar structure consisting of coarse and elongated grains, which results from the relatively slow cooling rate during casting. As one of the methods for refining of the α -Al grains in as-cast Al, addition of refiners such as Al-Ti, Al-Ti-B, and Al-Ti-C system alloys has been carried out.^[1–62] The addition of refiners introduces a large number of particles such as Al_3Ti , TiB_2 , or TiC into the Al melt, and these particles act as nuclei for α -Al grains. As a result, equiaxed and fine grain structures are promoted during solidification.

The addition of heterogeneous nuclei to achieve the grain refinement was first proposed by Cibula.^[1] The study on nucleation of Al by several intermetallic compounds such as Al_3Ti , Al_3Zr , AlB_2 , and Al_3Ni was carried out by Marcantonio and Mondolfo.^[7] The grain refinement of pure Al cast by Al-transition metal alloys such as Al-6mass%Ti, Al-4mass%B, Al-20mass%Cr, Al-10mass%Mo, Al-9mass%V, and Al-5mass%Zr alloys was studied by Warr et al.^[13] Although Al-Ti alloy shows the grain refining performance, small or no effect was found for Al-20mass%Cr, Al-10mass%Mo, Al-9mass%V, and Al-5mass%Zr alloys. On the other hand, Si is known to be a typical element that can poison grain refinement with the addition of an Al-5Ti-B master alloy.^[24,51,58] A number of studies have been carried

out to identify the mechanism of α -Al nucleation, and different mechanisms and theories have been hypothesized but many have been contradicted. Some examples are as follows:

Carbide-Boride Particle Theory

Stable and insoluble TiC and TiB_2 particles in the Al melt act as heterogeneous nucleation sites.^[1,2,9] According to classical nucleation theory, the formation of a stable nucleus depends on the competition between the driving force for the phase transformation from liquid to solid (the volume free energy) and the energy required for the formation of a new interface. The free energy barrier for nucleation on a heterogeneous substrate, $\Delta G_{\text{hetero}}^*$, can be described by^[37,63,64]

$$\Delta G_{\text{hetero}}^* = \frac{16\pi(\gamma_{LC})^3 T_M^2}{3L^2 \Delta T^2} \left\{ \frac{(2 + \cos\theta)(1 - \cos\theta)^2}{4} \right\} \quad (1)$$

Where γ_{LC} is the interfacial free energy of the liquid/crystal interface, T_M is the equilibrium melting temperature, L is the latent heat of solidification, ΔT is the undercooling below the liquidus temperature, and θ is the wetting angle between the liquid phase and the heterogeneous nucleation substrate, as shown in Fig. 1a. According to Eq. 1, the free energy barrier for nucleation is decreased by increasing the undercooling or by decreasing the wetting angle of the heterogeneous substrate. However, it was observed that

Fig. 1 Schematic illustrations of grain refinement mechanisms and theories by addition of refiners. (a) Schematic representation showing the formation of a spherical nucleus of crystal on the substrate. Where θ is the wetting angle, γ_{LC} , γ_{CS} , and γ_{LS} are interface free energies per unit area between liquid and crystal, between crystal and substrate, and between liquid and substrate, respectively. (b) Al-rich side of the Al-Ti equilibrium phase diagram with expected microstructures.^[23,65] (c) Model of the peritectic hulk theory. (d) Model of the duplex nucleation theory. Relative values of the interatomic spacings in the close-packed planes of Al, TiB_2 , and Al_3Ti phases are shown in right figure. Right diagram also shows schematically how the spacing in the Al_3Ti phase would change by changing the coatings thickness. (e) Solute concentration profile in front of a grain (left upper figure) and representation showing the constitutionally undercooled zone (left lower figure). ΔT_C is the difference between the actual temperature in the melt and the equilibrium liquidus temperature, as shown in right figure

the TiB_2 particles are pushed to grain boundaries, which suggests that the interfacial energy between the TiB_2 particle and Al is large.^[23] It contradicted the carbide-boride particle theory.

Peritectic Theory, Phase Diagram Theory

This theory attributes grain refinement to the peritectic reaction in the Al-Ti phase.^[3,12] Figure 1b shows Al-rich side of the Al-Ti equilibrium phase diagram.^[23,65] The following peritectic reaction occurs below in the Al-Ti phase diagram:

An Al_3Ti phase and liquid phase will together form an $\alpha\text{-Al}$ phase at 665 $^{\circ}\text{C}$, and the newly formed $\alpha\text{-Al}$ will envelope the Al_3Ti particles, as also shown in Fig. 1b. This reaction is believed to be a powerful nucleation mechanism yielding $\alpha\text{-Al}$, when a stable substrate is available for heterogeneous nucleation.

However, since the amount of Ti addition to the Al melt by the refiners is less than 0.01mass%, which is much lower than the Ti level required for peritectic reaction (0.15mass%), as shown in Fig. 1b, Al_3Ti particles dissolve rapidly in Al melts, as predicted by the phase diagram. Nevertheless, boron causes a shift in the peritectic composition of the liquid to lower Ti level so that the peritectic reaction can occur.^[8]

Heterogeneous Nucleation on Al_3Ti Particles

Al_3Ti particles in the Al melt act as the heterogeneous nucleation sites.^[8,10,13,15] Warr et al. have reported that Al_3Ti particles were commonly nucleant in both Al-Ti and Al-Ti-B refiners containing more than 0.2 mass%Ti.^[13] Grain refinement of the Al is due to nucleation by Al_3Ti crystals, but equilibrium conditions are obtained only in alloys in which Al_3Ti is primary. Grain refinement in alloys outside the Al_3Ti primary field is due to nonequilibrium conditions.^[8] Although Al_3Ti particles can act as the nucleation sites for Al when they exist in the liquid, the dissolution rate of Al_3Ti particles is much faster than the decomposition rate of TiC.^[15]

Peritectic Hulk Theory

Al_3Ti is a more potent nucleant than the TiB_2 and attempted to explain how the TiB_2 increases the stability of Al_3Ti . Figure 1c shows the model of the peritectic hulk theory. The protective TiB_2 forms a shell around the Al_3Ti , and slows down dissolution of the Al_3Ti , as diffusion needs to proceed through the TiB_2 shell.^[23,31,62] The Al_3Ti finally dissolves and leaves a cell of liquid with approximately the peritectic composition inside the TiB_2 shell. The peritectic reaction can then take place to form the $\alpha\text{-Al}$.^[23,31,62]

Duplex Nucleation Theory

TiB_2 crystal does not nucleate grain alone, but plays an indirect role in grain nucleation. In the presence of dissolved Ti, even below the peritectic composition, TiB_2 introduces an activity gradient with respect to Ti, leading to segregation of Ti atoms to the TiB_2 /melt interface (after Ref. [23], p. 2011). Then, precipitation of a thin layer of Al_3Ti occurs on the TiB_2 , and the formed Al_3Ti undergoes a peritectic reaction and thereby nucleates the solid.^[23] This theory is summarized in Fig. 1d.

The interatomic distances of Al and TiB_2 phases in close-packed planes are 0.286 and 0.303 nm, respectively, while the weighted average interatomic distance in close-packed plane of Al_3Ti phase is 0.275 nm. The coherent Al_3Ti layer with the TiB_2 substrate has an expanded interatomic distance, and the spacing relaxes toward the bulk value as the Al_3Ti layer becomes thicker, as illustrated schematically in Fig. 1d.^[30,34] Thus, the lattice matching of Al on the Al_3Ti layer is always better than that on TiB_2 .

Dendrite Remelting

Ohno and Sôda reported that the mechanism of the grain refinement is dendrite remelting due to the temperature fluctuations in the mold during the early stage of solidification.^[5]

Solute Theory

The grain refining involves not only potential nucleation, but also solute restriction of grain growth.^[31,32] The model of grain growth restriction leading to a finer grain size has been demonstrated by Vandyoussefi et al.^[36] The effect of solute on the grain size of a casting can be quantified by the growth restriction factor, Q , given as follows:^[12,21,31,35–37,46,55]

$$Q = m(k - 1)C_0 \quad (3)$$

In this equation, m is the phase-diagram liquidus slope (the change in liquidus temperature with solute content), C_0 is the concentration of the solute in the melt, and k is the partitioning coefficient, as shown in Fig. 1e. In this figure, ΔT_c is the solutal undercooling, and C_s^* and C_L^* are the equilibrium solute contents of the solid and liquid at the interface, respectively. When Q value is large, the rate of growth is small, thus allowing a large number of substrates acting as nucleating sites. Thus, the high value of Q is thought to be why titanium reduces the grain size dramatically even though the addition level is small.^[37] For an alloy with more than one solute, the overall Q value could be simply the sum of the values for the individual solutes.

In this way, a number of models have been proposed. However, it is clear that no completely satisfactory model exists.

CRYSTAL STRUCTURE AND SHAPE OF Al_3Ti IN Al-5MASS%Ti REFINER

Crystal Structure of Al_3Ti in Al-5mass%Ti Refiner

One of the important issues to consider in understanding grain refinement is the potency of the heterogeneous nucleation site. It is well accepted that an effective refiner contains heterogeneous nucleation sites having a good lattice registry with the metal matrix. The degree of disregistry between the heterogeneous nucleation site and the solidified phase, δ , proposed by Turnbull and Vonnegut^[66] is often used to discuss the effectiveness of heterogeneous nucleation site, and it can be calculated using the following equation:

$$\delta = (|a_s - a_c|/a_c) \times 100(\%) \quad (4)$$

Where a_s and a_c are the lattice parameters of the substrate particles and crystallized matrix phase without deformation, respectively. It is believed that a lower disregistry value between the low-index planes of adjoining phases is important. Generally, when disregistry value is less than 5%, the interface between the substrate and the matrix is coherent; when this value is between 5% and 25%, the

Fig. 2 Schematic illustrations of (a) Al with fcc structure and (b) Al_3Ti with D0_{22} structure

interface between the substrate and the matrix becomes partially coherent.^[67]

Figure 2a,b show the crystal structures of Al and Al_3Ti , respectively. The Al has fcc structure with lattice constant of $a=0.4049\text{ nm}$. On the other hand, Al_3Ti has a D0_{22} structure and its lattice parameters are $a=0.3851\text{ nm}$ and $c=0.8608\text{ nm}$. The atomic arrangements of Al superimposed on the atomic arrangements of the low-index planes of Al_3Ti are shown in Fig. 3.^[68] Since Al_3Ti has the low-symmetry tetragonal D0_{22} structure, Eq. 4 must be modified for application to two-dimensional lattices. The plane disregistry proposed by Bramfitt^[69] is

$$\delta_{(hkl)_{\text{Al}_3\text{Ti}}(hkl)_{\text{Al}}} = \frac{1}{3} \sum_{i=1}^3 \left\{ \left| \frac{d[uvw]_{\text{Al}_3\text{Ti}}^i \cos \theta - d[uvw]_{\text{Al}}^i}{d[uvw]_{\text{Al}}^i} \right| \right\} \times 100\%, \quad (5)$$

Where $(hkl)_{\text{Al}_3\text{Ti}}$ and $(hkl)_{\text{Al}}$ are the low-index planes of the Al_3Ti particle and Al, respectively, $[uvw]_{\text{Al}_3\text{Ti}}$ and $[uvw]_{\text{Al}}$ are the low-index orientations on $(hkl)_{\text{Al}_3\text{Ti}}$ and $(hkl)_{\text{Al}}$, respectively, $d[uvw]_{\text{Al}_3\text{Ti}}$ and $d[uvw]_{\text{Al}}$ are interatomic spacing distances along $[uvw]$, and θ is the angle between $[uvw]_{\text{Al}_3\text{Ti}}$ and $[uvw]_{\text{Al}}$. The plane disregistry values of possible crystallographic orientation relationships between Al_3Ti and Al shown in Fig. 3 at ambient temperature are presented in Table 1.^[70] Since the planar disregistry value between Al_3Ti and Al is smaller than 5%, it is possible for Al phase to nucleate on Al_3Ti particles. It must be noted that different crystallographic orientation relationship has different planar disregistry value.

However, the physical meaning of the plane disregistry is unclear. For example, it is unclear why three in-plane directions are considered when evaluating the plane disregistry. Kato has investigated the preferred epitaxial relationship (crystallographic orientation relationship) between

Fig. 3 Schematic representations showing lattice alignments of the low-index planes of Al_3Ti lattice with the orientation relations listed in Table 1, where the dotted lines indicate Al plane^[68]

the deposit and the substrate of metals using M , which is approximately proportional to the specific misfit strain energy.^[71–73] According to his study, the epitaxial relationship with small M values becomes the preferred one. The parameter M is defined as

$$M = \varepsilon_1^2 + \varepsilon_2^2 + (2/3)\varepsilon_1\varepsilon_2, \quad (6)$$

Where ε_1 and ε_2 are the principal misfit strains calculated from the principal distortions. Although this consideration has often been applied to epitaxial phenomena, it is potentially applicable to predicting the preferred orientation relationship between two solidified phases.^[74] M values of crystallographic orientation relationships shown in Fig. 3 were calculated, and the results are also listed in Table 1. The parameter M is readily applicable to predicting preferred orientation relationships between solidified Al and Al_3Ti . That is, favorable heterogeneous nucleation sites for casting could be predicted using the parameter M .

Shape of Al_3Ti in Al-5mass%Ti Refiner

It is known that the refining performance of the Al-Ti refiner is affected by the morphologies of the Al_3Ti particles.^[20,75,76] To study the morphologies of the Al_3Ti particles in the Al-5mass%Ti alloy, this alloy is centrifugally cast,^[77–81] and the microstructures of the cast fabricated under $G=30$ (G is the centrifugal force in units of gravity) observed on the radial plane and the radial plane are shown in Fig. 4a,b, respectively.^[78] Three-dimensional photograph showing the shape of the Al_3Ti particles in the centrifugally cast ring ($G=80$) is shown in Fig. 4c.^[80] The

shape of Al_3Ti particles in the Al-5mass%Ti alloy can be identified to be platelet judging from comparison among these figures. Coarse Al_3Ti platelet particles and small Al_3Ti particles were observed. Figure 4d shows the inverse pole figure map of the Al_3Ti phase in the centrifugally cast Al-5mass%Ti fabricated under applied centrifugal force of $120G$.^[81] This inverse pole figure map shows crystal plane orientation on the radial plane. It is seen that the Al_3Ti platelet face is $(001)_{\text{Al}_3\text{Ti}}$, which is in agreement with previous studies.^[12,82]

As mentioned above, the shape of Al_3Ti particles in the Al-5 mass% Ti ingot is platelet,^[77–82] and the face of Al_3Ti platelets is a $(001)_{\text{Al}_3\text{Ti}}$ plane.^[12,80–82] Therefore, the dominant face of Al_3Ti platelets is not the best plane for heterogeneous nucleation, since it has the largest planar discrepancy value among the above orientation relationships, as shown in Table 1. This is a reason why the refining performance of the Al-Ti refiner is affected by the morphologies of the Al_3Ti particles. Then, the facet Al_3Ti platelet, shown in Fig. 5a,^[83] will be used as a model structure. Figure 5b shows the area ratio plotted against the aspect ratio t/l .^[83] It is seen that the (001)-type surface becomes less dominant when the aspect ratio becomes higher. The average discrepancy value and average parameter M for the Al_3Ti platelets with different aspect ratios are calculated using Eqs. 5 and 6, respectively, and the results are shown in Fig. 5c,^[83] although the average discrepancy value and average parameter M themselves do not have physical meanings. If the Al_3Ti platelet has a larger aspect ratio, the average discrepancy value and average parameter M become smaller. However, the average discrepancy value for the platelet with an aspect ratio of 0.05 can be estimated to be 4.8%.

Fig. 4 Microstructures of the centrifugally cast Al-5mass%Ti alloy. SEM pictures taken on (a) the plane perpendicular to the rotation axis and (b) the plane perpendicular to the radial direction.^[78] Three-dimensional photograph showing the Al₃Ti particles^[80] and inverse pole figure map of the Al₃Ti phase on the plane perpendicular to the radial direction^[81] are shown in (c) and (d), respectively. The direction of centrifugal force in (a) and (c) is indicated by an arrow.

GRAIN REFINING PERFORMANCE BY EQUAL-CHANNEL ANGULAR-PRESSED Al-5mass%Ti REFINER

As described earlier, the Al₃Ti particles in Al-5mass%Ti refiner have large platelet shape, which leads to the limitation of grain refining performance of the Al-5mass%Ti refiner. It was reported by Baba and Hamada that the grain refining effect due to Al₃Ti particles became more pronounced as the particle diameter decreased.^[11] The grain refining performance could be improved by decreasing the size of Al₃Ti and increasing in the number density of nucleation sites in original Al-5mass%Ti refiner by using severe

plastic deformation (SPD) technique. At the same time, fragmentation of the Al₃Ti platelet can decrease the average disregistry value as a consequence of increasing the aspect ratio of Al₃Ti platelet.^[83] Numerous investigations have been carried out to produce ultrafine-grained microstructures using SPD technique. One of the most attractive SPD techniques is equal-channel angular pressing (ECAP), by which an intensive plastic strain can be imposed to bulk specimens.^[84–86] The ECAP was, therefore, conducted for Al-5mass%Ti-0.25mass%C and Al-5mass%Ti refiners at room temperature to decrease the size of Al₃Ti particles and to increase in the number of nucleation sites.^[87,88] During this process, the pressed sample was rotated 90°

Source: Modified from original figures appeared in Zhang, Z.; Hosoda, S.; Kim, I.S.; Watanabe, Y. Grain refining performance for Al and Al-Si Alloy casts by addition of equal-channel angular-pressed Al-5mass%Ti Alloy. *Mater. Sci. Eng. A* **2006**, A425, 55–63.

along the longitudinal axis in the same direction between consecutive passes through the die, which has been defined as route B_C.^[86]

Figure 6a–c shows the microstructures of the Al-5mass%Ti refiner before and after ECAP process with 8 and 15 passes, respectively.^[88] Large platelet shaped Al₃Ti particles with 70 μm in average length and 3.5 μm in average width were observed in the microstructure before ECAP. Therefore, initial aspect ratio of Al₃Ti platelet in the Al-5mass%Ti refiner is 0.05. The Al₃Ti particles cracked severely, and the particle size decreased progressively with increasing ECAP passes. The size change of the Al₃Ti platelets in the Al-5 mass%Ti refiner with ECAP passes is shown in Fig. 6d.^[88] There is a significant reduction trend in length of the Al₃Ti platelets by ECAP, and length of the Al₃Ti particles of 70 μm in original microstructure decreases to 3.2 μm by 15 passes of ECAP. The aspect ratio, t/l , for each ECAPed sample is calculated, and the results are also shown in Fig. 6d. It appears clearly that the aspect ratio increases with increasing the number of ECAP passes. This is due to the fact that the platelet-shaped Al₃Ti particles break easily in the direction of the length by the huge shear strain, which is introduced during the ECAP process.

Grain refining experiments were carried out using pure Al with 99.99% purity at 750°C. The mass fraction of Al-5 mass% Ti alloy as the additive is 0.5% and the resultant Ti concentration of the cast alloy is 0.025 mass%. The melt was cast after a holding time of 5 min. The macrostructures of pure Al cast samples are shown in Fig. 7.^[88] In case of the cast without the refiner addition, most of α-Al grains are columnar, and the mean size of the α-Al grains is very large, as shown in Fig. 7a. When the un-ECAPed Al-5mass%Ti alloy was added to

Fig. 7 Macrostructures of as-cast pure Al (a) without refiner and with ECAPed Al-5mass%Ti refiners of (b) 0 pass, (c) 8 passes, and (d) 15 passes.^[88] Mean grain size of α-Al grains and the Vickers microhardness (HV) of the Al casts refined by the ECAPed Al-5 mass%Ti refiner with ECAP passes are shown in (e).^[88]

Source: Modified from original figures appeared in Zhang, Z.; Hosoda, S.; Kim, I.S.; Watanabe, Y. Grain refining performance for Al and Al-Si Alloy casts by addition of equal-channel angular-pressed Al-5mass%Ti Alloy. *Mater. Sci. Eng. A* **2006**, A425, 55–63.

the pure Al melt, as shown in Fig. 7b, the cast has coarse α -Al columnar grains and a few fine equiaxed grains, and its grain size is smaller than that without the refiner addition, shown in Fig. 7a. It must be noted here that when the ECAPed Al-5mass%Ti alloy was added to the pure Al melt, the macrostructures showed mostly very fine equiaxed α -Al grains and some fine columnar, as shown in Fig. 7c,d. Furthermore, the finer α -Al grains were formed in the casts refined by the Al-5mass%Ti refiner with larger number of ECAP passes, as shown in Fig. 7e.^[88] Vickers microhardness (HV) values of the casts refined by ECAPed Al-5mass% Ti refiner are also shown in Fig. 7e.^[88] From this figure, the HV value increased considerably by increasing the number of ECAP passes to the Al-5mass% Ti refiner. This is because the grain boundaries of the α -Al grains increased significantly when the α -Al grains were refined in a large degree. The application of the ECAP technique to Al-Ti refiner will be expected to have a very useful practical application in refining industrial Al alloys.^[59,87,88]

GRAIN REFINING PERFORMANCE BY COLD-ROLLED Al-5MASS%Ti REFINER

Although ECAP can give severe plastic strain to metallic material, it is difficult to apply the ECAP to the industrial manufacture. Effects of hot rolling and heat treatment of Al-5Ti-1B refiner on the grain refining efficiency of Al were studied by Venkateswarlu et al.^[38] Since cold rolling is also expected to be a useful process to improve the effectiveness of refiners in industrial applications, Al-5mass%Ti refiner having a thickness of 10mm was cold rolled to reduction ratios of 17%, 33%, 45%, and 53% with several passes. Figure 8a,b show the microstructures of the cold-rolled Al-Ti refiner with reduction ratios of 17% and 53%, respectively,^[70] where rolling direction (RD) and normal direction (ND) correspond to the horizontal direction and the vertical direction in the figures, respectively. As can be seen, the Al_3Ti particles in the Al-Ti refiner are fragmented and aligned with the RD as the reduction ratio increases.

To discuss the above phenomena quantitatively, mean size of Al_3Ti particles and the Hermans orientation parameter f_p were evaluated for the cold-rolled Al-Ti refiner, and the results are shown in Fig. 8c,^[70] where the Hermans orientation parameter f_p can be calculated by^[74,78,79,89,90]

$$f_p = [2 \langle \cos^2 \theta \rangle - 1]. \quad (7)$$

θ in Eq. 7 is the angle between the RD and the longitudinal axis of an Al_3Ti platelet particle or an Al_3Ti particle group, as shown in Fig. 8a. The trigonometric average is given by:

Fig. 8 SEM photographs of cold-rolled Al-5mass%Ti refiner with reduction ratios of (a) 17% and (b) 53%.^[70] Horizontal and vertical directions are RD and TD, respectively. Mean size (d_{Al_3Ti}) and orientation parameter (f_p) of Al_3Ti particles in cold-rolled Al-Ti refiner as a function of the reduction ratio of cold rolling are shown in (c).^[70]

Source: Modified from original figures appeared in Sato, H.; Ota, K.; Kato, H.; Furukawa, M.; Azuma, M.; Watanabe, Y.; Zhang, Z.; Tsuzaki, K. Grain refinement of as-cast pure Al by cold-rolled Al-Ti alloy refiner. Mater. Trans. **2013**, 54 (9), 1554–1561.

$$\langle \cos^2 \theta \rangle = \int_{-\pi/2}^{\pi/2} \cos^2 \theta n(\theta) d\theta. \quad (8)$$

The term $n(\theta)$ is the orientation distribution function that specifies the fraction of Al_3Ti platelets within the angular element $d\theta$. The parameter f_p becomes 0 for a random distribution of orientations, and it becomes 1 for perfect alignments of the longitudinal axis with the RD. It is seen from Fig. 8c that the mean size of Al_3Ti particles decreases whereas the f_p increases as the reduction ratio increases.^[70] However, these values reach constant values at a reduction ratio of 45%. Namely, refinement of the Al_3Ti particles does not occur at high reduction ratios because of the alignment of the longitudinal axes of Al_3Ti particles with the RD.

To evaluate the grain refining performance, casting tests were carried out using an Al ingot with 99.99% purity and the cold-rolled Al-Ti alloy refiner with reduction ratios between 0% (nondeformed) and 53%, here the amount of Al-Ti refiner was 0.8 mass% (Ti: 0.04 mass%). The macrostructures of the as-cast pure Al with and without the cold-rolled Al-Ti refiner are shown in Fig. 9a–c.^[70] The pure Al sample cast without the refiner shown in Fig. 9a has a typical columnar structure, whereas those with the refiner have equiaxed grains and become finer as the reduction ratio of the cold-rolled refiners increases, as shown in Fig. 9b,c. It is

Fig. 9 Macrostructures of as-cast pure Al (a) without refiner and with refiners cold rolled with reduction ratios of (b) 0%, and (c) 53%.^[70] (d) Mean grain size of α -Al grains and the Vickers hardness (HV) of the Al casts refined by the cold-rolled Al-5 mass%Ti refiner.^[70]

Source: Modified from original figures appeared in Sato, H.; Ota, K.; Kato, H.; Furukawa, M.; Azuma, M.; Watanabe, Y.; Zhang, Z.; Tsuzaki, K. Grain refinement of as-cast pure Al by cold-rolled Al-Ti alloy refiner. *Mater. Trans.* **2013**, 54 (9), 1554–1561.

noted that the cold-rolled refiner with larger reduction ratio could achieve both the grain refinement performance of the α -Al grains and the microstructural homogenization of the as-cast pure Al.

The mean size of α -Al grains in pure Al cast refined by cold-rolled Al-5mass%Ti refiner plotted against the reduction ratio is shown in Fig. 9d.^[70] As the reduction ratio increases, d_{cast} decreases continuously from about 700 to 350 μm , but becomes saturated at a reduction ratio of 45%. The HV of the as-cast pure Al refined by cold-rolled Al-5mass%Ti refiner as a function of the reduction ratio is also shown in Fig. 9d. Since the hardness of the as-cast pure Al without refiner was 18.8, all of the pure Al casts refined by Al-Ti refiners had higher hardness. Moreover, the hardness of the pure Al cast increased as the reduction ratio of the refiners increased. This improvement in the hardness of the pure Al cast arises from grain refinement.

FRAGMENTATION BEHAVIOR OF Al_3Ti PLATELETS IN Al-Ti REFINER BY FRICTION STIR PROCESSING

Friction stir welding (FSW) is a solid-state joining technique, where a nonconsumable rotating tool with a specially designed probe (pin) and shoulder is inserted into the abutting edges of the workpieces to be joined and traversed along the joint line.^[91–94] Then the material is softened by frictional heating, and the forging pressure from the shoulder reconsolidates the material behind the tool. It is known that joining process by FSW can be performed with low heat input, and can be applied for various materials. Friction stir processing (FSP) is a variant of FSW that involves traversing of the friction stir tool through the material in the absence of a joint interface.^[93] Since FSP could cause SPD in the sample, the Al_3Ti platelets in the Al-5mass%Ti refiner could be fragmented by SPD.^[95]

Fig. 10 Micrograph showing microstructure of the Al-5mass%Ti refiner at FSPed position.^[95] Broken line presents the position of the rotation tool probe

Source: Sato, H.; Miyamoto, Y.; Watanabe, Y.; Natio, Y.; Nose, T. Fragmentation behavior of Al_3Ti particles in Al- Al_3Ti composite deformed by FSP. *Proceedings of the 1st International Joint Symposium on Joining and Welding*, Osaka, Japan, November 6–8, 2013; Fujii, H., Ed; Woodhead Publishing: Oxford, 2013, 453–458.

FSP was performed by the high-speed steel tool, where the diameters of a shoulder and a probe of the tool were 15 and 4 mm, respectively. Rotation speed and traveling speed of the tool were 400rpm and 50 mm/min, respectively. Figure 10 shows microstructure of the friction stir processed Al-5mass%Ti refiner.^[95] Broken line in this figure corresponds to the position of the rotating tool probe, where the fragmented Al_3Ti particles are randomly distributed. These particles are much smaller than those in the other region and its shape is granular. It is also found that the size of the Al_3Ti particles at the advancing side is smaller than that at the retreating side. Furthermore, Al_3Ti particles at center and center-bottom of the tool probe have almost same size with that at the advancing side. Morisada et al. have mentioned that the probe is subjected to larger stress at the advancing side during FSW due to the tool traveling.^[96] As well as the advancing side, it is considered that such large stress is caused at the center and the center-bottom parts of the tool probe. This is because that compression stress would occur at these parts. Consequently, the sizes of the Al_3Ti particles become smaller at the advancing side, the center, and the center-bottom parts, since larger shear strain is introduced at these parts. Sliding wear can also induce such SPD at the sample surface, and fragmentation behavior of Al_3Ti platelets in Al-Ti alloys by wear is reported in some literatures.^[77,80,97]

GRAIN REFINEMENT PERFORMANCE BY Al-10VOL%Ti REFINER

The refining performance of the Al-Ti refiner is affected by the morphologies of the Al_3Ti particles,^[20,75,76] and the spherical and grain-shaped Al_3Ti particles have a smaller average disregistry value compared with the platelet-shaped Al_3Ti particle found in Al-Ti refiner.^[83] The grain-shaped Al_3Ti particle can be obtained by the reaction between grain-shaped Ti particles and molten pure Al. With the in mind, Al-10vol%Ti refiner has been fabricated by sintering of mixed powder of grain-shaped Ti particles and Al

particles at lower temperature for shorter time, which can be obtained by spark plasma sintering (SPS) method.^[68]

Figure 11a shows a micrograph of fabricated Al-10vol%Ti refiner.^[68] As can be seen, the grain-shaped Ti particles are distributed within the matrix homogeneously. Clear interface is observed between Ti particles and Al matrix, and no reaction can be recognized. In this way, the grain-shaped Ti particles successfully coexist with Al matrix without any reaction by using SPS method. However, when the Al-Ti refiner has been also subjected to isothermal heat treatment at 600°C for 24h, reacted Al_3Ti particles are formed in the Al matrix, as shown in Fig. 11b.^[68] Therefore, it is expected that the grain-shaped Al_3Ti particles could be formed during the casting process, and it acts as a good nucleation site for solidification of Al.

The Al-10vol%Ti refiner of 1.2 g was added to molten pure Al of 148.8 g at 750°C. After addition of refiner into the melt, stirring for 30s and holding the melt from 0 to 120min, it was poured into a mold. Figure 12a shows the macrostructure of Al cast without refiner, and it has a relatively large grain size.^[68] Although addition of sintered Al particles sample does not show grain refinement performance, as shown in Fig. 12b,^[68] the Al casts with Al-10vol%Ti refiner have equiaxed and fine microstructure, as shown in Fig. 12c,d,^[68] where holding times are 0 and 30 min, respectively. Therefore, grain-shaped Al_3Ti particles, formed by reaction of $3\text{Al} + \text{Ti} \rightarrow \text{Al}_3\text{Ti}$, become good nucleation sites for solidification of Al, while Al_2O_3 phase on the surface of Al particles does not.

The mean grain size of α -Al grain as a function of holding time for the casts refined by the Al-10vol%Ti refiner is shown in Fig. 12e.^[68] It is seen from this figure that the grain size decreases at the initial period of holding time and then increases. The highest grain refinement performance is found for holding time of 30min, which is relatively long compared to other refiners. This is because the reaction needs an incubation period. A significant fading effect is found, since the formed Al_3Ti phase decomposed into molten Al.

Source: Modified from original figures appeared in Watanabe, Y.; Hamada, T.; Sato, H. Fabrication of novel Al- L_{12} -type $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ refiners by spark plasma sintering and their refining performance. *Jpn. J. Appl. Phys.* **2016**, 55 (01AG01), 1–10.

GRAIN REFINING PERFORMANCE BY AI- L_{12} -TYPE $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ REFINER

It is known that alloying with a certain amount of a transition element, such as Cr, Mn, Fe, Co, Ni, and Cu causes the transformation from the D_{022} -type tetragonal structure of Al_3Ti to a high-symmetry L_{12} cubic structure.^[98,99] This transformation increases the symmetry of Al_3Ti intermetallic compounds, which results in the constant lattice registry with the metal matrix when they are used as heterogeneous nucleation sites. Moreover, since the lattice constant of $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ intermetallic compound with the L_{12} structure is $a=0.393$ nm, smaller disregistry values between $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ intermetallic compound and Al, that is 2.95%, can be achieved. Therefore, it is expected that the $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ intermetallic compound particles with the L_{12} structure will become favorable heterogeneous nucleation sites for an Al cast.^[83,100]

Two types of $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ intermetallic compound particles with the L_{12} structure were prepared. One was crushed particles shown at the upper right of Fig. 13a,^[83] which was prepared by the mechanical crushing of a bulk $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ intermetallic compound. The bulk sample was prepared by an arc melting method and was homogenized at 1200°C for 72 h. Another type was directly prepared by gas atomization, as shown in upper right of Fig. 13b.^[83] Both crushed and gas-atomized particles were sieved into the size of 75–150 μm , and sieved particles are mixed with pure Al particles (106–180 μm), where the volume fraction of $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ particles was 10 vol%. Sintering of the mixed powder using an SPS apparatus was performed at 500°C for 5 min under an applied stress of 45 MPa. The microstructures of the fabricated novel refiners with crushed and gas-atomized L_{12} -type $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ particles are shown in Fig. 13a,b, respectively.^[83] It is seen from these figures

that the granular or spherical particles are successfully embedded within the Al matrix homogeneously.

By using the novel Al-Li₂-type Al_{2.7}Fe_{0.3}Ti refiners, the grain refining performance was studied. Pure Al ingot (99.99%, 148.8 g) was melted at 750°C, and after the addition of 1.2 g of refiner into the melt, the melt was homogenized for 30s by mechanical stirring. It was held for a certain time at 750°C (holding time) and then poured into a steel mold. Figure 14b–d shows the macrostructures of the Al cast refined by a refiner with crushed particles, whereas those by a refiner with gas-atomized particles are shown in Fig. 14e–g, where the holding time of (b) and (e) is 0s, (c) and (f) is 600s, and (d) and (g) is 1200s.^[83] For comparison, the macrograph of an unrefined pure Al cast is shown in Fig. 14a.^[83] The Al cast without a refiner shown in Fig. 14a has coarse and inhomogeneous grains, and the average grain size is about 3690μm. On the contrary, the average grain size is smaller and the grains are more homogeneous in the Al cast with the Al-Li₂-type Al_{2.7}Fe_{0.3}Ti refiners. In this way, the Li₂ type Al_{2.7}Fe_{0.3}Ti particles can become favorable heterogeneous nucleation sites for the Al cast. The results of quantitative analysis of the average grain size are shown in Fig. 14h as a function of holding time.^[83] It is seen that the superior grain refining efficiency is found for the refiner with gas-atomized particles compared with the refiner with crushed particles. This is because the surfaces of the crushed particles are covered

by the retained secondary phase, which may lead to worse disregistry, while the secondary phase is mainly located inside the gas-atomized particles. The grain size of the sample cast with both refiners reaches a minimum at 600s and then has an ascending trend with holding time. Since the Al_{2.7}Fe_{0.3}Ti phase cannot exist within the Al matrix in equilibrium,^[100] this may result in the fading behavior.

CONCLUSIONS

In this chapter, grain refinement performance of cast Al by heterogeneous nucleation sites of Al₃Ti and Li₂-type Al_{2.7}Fe_{0.3}Ti particles with small disregistry values is reviewed. The major conclusions are summarized below:

1. Al₃Ti has a D0₂₂ structure, and the shape of Al₃Ti particles in the Al-5mass%Ti alloy is platelet with (001)_{Al₃Ti} platelet face. Since the dominant face of Al₃Ti platelets has the largest planar disregistry value among the reported orientation relationships, it is not the best plane for heterogeneous nucleation. This is a reason why the refining performance of the Al-Ti refiner is affected by the morphologies of the Al₃Ti particles.
2. Large platelet Al₃Ti particles in Al-Ti refiner cracked severely with increasing ECAP passes, and the aspect

Fig. 14 Macrostructures of (a) unrefined pure Al cast and refined casts by the novel Al-Li₂-type Al_{2.7}Fe_{0.3}Ti refiners with (b)–(d) crushed particles and (e)–(g) gas-atomized particles, where the holding time of (b) and (e) is 0s, (c) and (f) is 600s, and (d) and (g) is 1200s.^[83] Average grain size as a function of holding time is shown in (h)^[83]

Source: Modified from original figures appeared in Watanabe, Y.; Hamada, T.; Sato, H. Fabrication of novel Al-Li₂-type Al_{2.7}Fe_{0.3}Ti refiners by spark plasma sintering and their refining performance. *Jpn. J. Appl. Phys.* **2016**, 55 (01AG01), 1–10.

ratio increases with increasing the number of ECAP passes. The Al-Ti refiner appeared to have a better grain refining effect after ECAP than before ECAP with a refiner addition.

3. Al_3Ti platelet particles in the Al-Ti refiner were fragmented by cold rolling. As the reduction ratio of the cold rolling increased, the size of the Al_3Ti platelet particles decreased and the number density of the particles increased. The size of $\alpha\text{-Al}$ grains in the pure Al cast refined by cold-rolled Al-Ti refiner decreased as the reduction ratio of the cold-rolled refiners increased.
4. The Al_3Ti particles in Al-Ti refiner can be fragmented by the shear deformation induced by FSP. The size of Al_3Ti particles at the advancing side is smaller than that at the retreating side, since the shear strain induced by FSP is larger at the advancing side rather than at the retreating side.
5. Grain refining performance was found for Al cast by addition of Al-10 vol%Ti refiner, since grain-shaped Al_3Ti particles, formed by reaction of $3\text{Al} + \text{Ti} \rightarrow \text{Al}_3\text{Ti}$, become good nucleation sites for solidification of Al. On the other hand, addition of sintered Al particles sample does not show improved grain refinement performance.
6. The L1_2 -type $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ particles can become favorable heterogeneous nucleation sites for the Al cast, since the disregistry between $\text{Al}_{2.7}\text{Fe}_{0.3}\text{Ti}$ and Al is small. Superior grain refining efficiency is found in the refiner with gas-atomized particles compared with the refiner with crushed particles, since the surfaces of crushed particles are covered by the retained second phase, while the second phase in gas-atomized particles is mainly located inside the particles.
7. The above ideas can be applied not only for Al cast but also for Fe, Mg,^[101] Ti, Cu, and Zn casts.

Abstract

Graphene materials with excellent mechanical and physical properties as well as two-dimensional flexible morphology are attractive reinforcement nanofillers for aluminum matrix nanocomposites. Rapid progress in graphene materials and nanocomposites fabricating technology promotes the development of advanced graphene-reinforced aluminum matrix nanocomposites for structural and functional applications. Nevertheless, the dispersion of graphene nanofillers within aluminum matrix and the interfacial controlling between them remain long-standing challenges in the fabrication of graphene-reinforced aluminum matrix nanocomposites. This article focuses on the recent development of the fabrication and characterization of graphene-reinforced aluminum matrix nanocomposites, including the dispersion and consolidation technology of graphene-reinforced aluminum matrix nanocomposites as well as their structural characters and mechanical behaviors.

Keywords: Aluminum matrix nanocomposites; Dispersion process; Fabrication process; Graphene materials; Interfacial bonding; Mechanical properties; Reinforcing mechanism.

INTRODUCTION

Graphene materials have been drawing extensive researching attention over recent years as a promising material potentially, and would influence the world in the next 20 years remarkably. Their physical and chemical properties, such as mechanical, thermal, electrical, magnetic, optical, acoustic, etc., have been extensively investigated in the last decades. Due to their sp^2 -hybridized two-dimensional (2-D) thin-layer structure, graphene materials can provide us extraordinary strength, thermal and electric conductivity, light transparency, and light weight. In virtue of their outstanding and unique properties, graphene materials have great application potential in both traditional and emerging fields, such as energy, biotechnology, water resources, electronic and network technology, aerospace and automotive industries, etc.

Aluminum and its alloys have been extensively utilized in the fields of aeronautical, aerospace, automobile, transportation, and electronic industries, as a result of their low cost, low density, high specific strength, and good ductility properties. However, ordinary aluminum alloy materials cannot meet the need of rapid development of modern industry technology. Considerable effort has been paid to improve the mechanical performances of aluminum alloys using the traditional processes, such as alloying

elements adjustment, heat treatment, and deformation process. Although great progress has been achieved through conventional ways, realizing a jumping improvement on the mechanical performance of aluminum alloys is still challenging. Carbon filler reinforcement is an effective approach to improve the strength and stiffness of aluminum and its alloys, among which carbon fibers- or carbon nanotubes (CNTs)-reinforced aluminum matrix composites were extensively investigated. Compared with carbon fibers and CNTs, graphene materials possess higher strength, higher modulus, larger specific surface area (SSA), and flexible morphology, which make graphene-reinforced aluminum matrix nanocomposites a promising candidate for the next-generation aluminum matrix composites. It is worth noting that, comparing with particulate and fibrous reinforcements, the unique 2-D structure of graphene would bring some new strengthening and toughening mechanisms. What is more, the significantly potential advantages of graphene materials in optical, thermal, and electrical performance are expected to functionalize graphene-reinforced aluminum matrix nanocomposites and turn it to a new kind of structural-functional material.

In the last 5 years, as a result of the rapid development in graphene materials fabricating and dispersing technology, some pioneering works were carried out on the incorporation of graphene materials into aluminum matrix.

Graphene materials are found highly efficient in strengthening the matrix aluminum. The mechanical properties such as tensile strength and yielding strength increase significantly with small amounts of graphene addition. Importantly, some results reported show the elongation of the graphene-reinforced aluminum matrix nanocomposites does not decrease after introducing graphene nanofillers. These remarkable advantages in mechanical performance give graphene-reinforced aluminum matrix nanocomposites huge application prospects in the fields of aeronautical, aerospace, and automotive industries. This article would focus on the recent development on the fabrication process and characterization technology of graphene-reinforced aluminum matrix nanocomposites, including the dispersion and consolidation technology of graphene-reinforced aluminum matrix nanocomposites as well as their structural characters and mechanical behaviors.

FABRICATION OF GRAPHENE-REINFORCED ALUMINUM MATRIX NANOCOMPOSITES

Graphene is the name given to a flat monolayer of carbon atoms tightly packed into a 2-D honeycomb lattice.^[1] Graphene materials is the collection of 2-D graphene-based materials including single-, double-, and few (3 to <10)-layer graphene; chemical-modified graphene and materials made from graphene precursors. Since first measurably produced and isolated by scientists of Andre Geim and Konstantin Novoselov with micromechanical cleavage or scotch tape technique in 2003,^[2] several fabricating routes have been developed; they are (i) mechanical cleavage, (ii) chemical vapor deposition (CVD), and (iii) chemical exfoliation and synthesis. Mechanical cleavage produces graphene with the lowest number of defects and highest electron mobility,^[3] where graphene layers are exfoliated from graphite-based materials by

mechanical forces. Scotch tape,^[4] wedge-based mechanical exfoliation,^[5,6] shearing exfoliation,^[7] ball milling exfoliation,^[8] and sonication exfoliation^[9,10] fall into this category. CVD method synthesizes graphene with a large scale (several inches scale), the graphene is deposited on the top of a special substrate such as SiC,^[11] copper,^[12,13] or nickel^[14,15] film. The quality of graphene materials fabricated by mechanical cleavage and CVD routes is generally very high. However, their yield is relatively low and cost is significantly high, which greatly restricts their industrial application potential. The other approaches can be classified into chemical exfoliation and synthesis route, such as graphene intercalation,^[16] graphene oxide reduction,^[17] nanotubes slicing,^[18,19] sugar method,^[20] carbon dioxide reduction,^[21] etc. In this route, graphene materials are fabricated through various chemical means, either derived from graphene intercalation compound or sliced from nanotubes or bottom-up synthesized from sugar, carbon dioxides and the like carbon resources, and some of these approaches have yet to achieve output sufficient for commercialization. Graphene intercalation^[22] (Fig. 1) and graphene oxide reduction approaches have been reported for the industrially fabrication of few-layer graphene with good hydrophilic property and significant large size,^[23] which is suitable for the application in composites as nanofillers. Single-layer graphene is the strongest material ever tested, with an intrinsic tensile strength of 130 GPa and a Young's modulus (stiffness) of 1 TPa (150000000 psi),^[24] while few-layer graphene possesses similar mechanical properties. The Young's modulus of graphene bilayer and trilayer was measured to be 1.04 and 0.98 TPa, while the intrinsic tensile strength to be 126 and 101 GPa, respectively.^[25] Despite its strength, graphene is also relatively brittle, with a fracture toughness of $\sim 4 \text{ MPa} \sqrt{\text{m}}$.^[26] And the mechanical properties of the bulk materials of graphene remain disappointing.^[27] It has been predicted that graphene can significantly outperform CNTs in many

Fig. 1 Transmission electron micrograph of graphene platelet via intercalation route showing the wrinkled morphology. Inset shows the selected area diffraction pattern (SADP) of the hexagonal graphene cell^[22]

respects.^[28–30] One possible route to get excellent properties for practical application would be incorporating graphene in composite materials.

The progress in graphene materials fabricating technology promotes the research studies on graphene-reinforced aluminum matrix nanocomposites vigorously. In the recent years, a gradually increasing number of research works are available in the literature on the processing and properties of nanocomposites reinforced with graphene and its derivatives such as exfoliated graphene and reduced graphene oxide. However, the incorporation of graphene materials into the metal matrix remains challenging as a result of the harsh conditions involved in the fabrication processing.^[31] The main difficulties for the development of graphene-reinforced aluminum matrix nanocomposites include (i) the achievement of perfect dispersion of graphene materials into the aluminum metal matrix, (ii) the realization of appropriate interfacial bonding between graphene nanofillers and aluminum matrix, (iii) the conservation of graphene nanofillers without damaging its structure during synthesis process at the correspondent consolidating and deforming temperature. The first challenge comes from a common issue for nanoscience and technology, that is, nanofillers generally tend to agglomerate as a result of the interaction among them. Graphene materials have very large SSAs, single-layer graphene has a theoretical $SSA = 2630 \text{ m}^2/\text{g}$,^[32] which is much larger than the reported value for carbon black (typically smaller than $900 \text{ m}^2/\text{g}$) or for CNTs, from ≈ 100 to $1000 \text{ m}^2/\text{g}$,^[33] and is similar to activated carbon (carbon processed with oxygen to make it porous).^[32,34] These graphene nanofillers tend to overlap each other for reducing their surface energy, which leads to the agglomeration during fabricating nanocomposites and brings disadvantages to the mechanical properties. Besides, the large difference in density between aluminum and graphene nanofillers multiplies the difficulties for their uniform dispersion. To conquer this dispersion puzzle, several strategies containing mechanical stirring, ultrasonic dispersion, ball milling, planetary milling, surface modification, and electrostatic adsorption were adopted in the reported literature studies. The other two challenges come from the issue of suppressing chemical reaction between aluminum and carbonaceous materials. Despite the fact that the carbon solubility in aluminum is relatively low within a wide temperature range, for instance, the value is only around 6–12 ppm even at 1000°C , which is far above aluminum melting point.^[35,36] These two elements together are thermodynamically unstable especially when aluminum is melt, and the formation of needle-shape aluminum carbide has been confirmed according to the following formula $4\text{Al} + 3\text{C} \rightarrow \text{Al}_4\text{C}_3$.^[37] Aluminum carbide phase is brittle and sensitive to moisture, which would result in the pulverization of bulk material in an ambient environment. To avoid the introducing of harmful aluminum carbide phase, surface modification of the carbonaceous nanofillers (such as nickel/copper coating), alloying

constituent modification of the matrix alloy (e.g., adding silicon/titanium), or restricting fabrication temperature were utilized. Among them, low-temperature powder metallurgic method is an ideal candidate for the fabrication of graphene-reinforced aluminum matrix nanocomposites. These low-temperature synthesis processes have the advantages not only on the interfacial controlling but also on the grain size restricting. Accordingly, the nanocomposites produced by low-temperature processes generally possess higher mechanical properties over other technologies.

Powder metallurgy is a versatile process for manufacturing metal matrix composites with graphene nanofillers due to its simplicity, flexibility, and near-net-shape capability.^[38] The process involves mechanical blending of nanofillers with metal or alloy powders in a milling jar, followed by compaction and sintering, cold isostatic pressing, hot pressing (HP), hot isostatic pressing (HIP), or spark plasma sintering (SPS). In certain cases, secondary mechanical deformation treatments such as hot extrusion, hot forging, and hot rolling are employed to further consolidate the compacts into full-dense products.^[38]

Blending Processes

As is well known, the effective dispersion of nanofillers in matrix is the first hard task for nanocomposites fabrication. The results are generally poor by simply mixing metal aluminum powders with carbonaceous nanofillers such as graphene or CNTs, because van der Waals forces among nanofillers are insufficient to be broken up by conventional mixing method and mechanical forces.

To achieve a better dispersion, high-energy milling processes especially ball milling and planetary milling are most commonly applied in the literature research studies. In these processes, the mixture powder materials are charged into a milling jar containing stainless steel or ceramic milling balls and undergo random impaction from these balls. Consequently, homogeneous mixing and even bonding of the constituent powder particulates on an atomic scale is achieved during their repeating deforming, fracture, and cold welding processes. By tailoring the milling parameters (e.g., ball to powder weight ratio, milling atmosphere, agent, speed, and duration), a various degree of supersaturated solid solutions, metastable crystallization, alloys amorphization, and grain size refinement can be introduced. Wet ball milling with liquid milling media is more favorable to obtain better dispersion in ball milling practices. Therefore, some organic solvents (such as ethanol, acetone, N-methyl-2-pyrrolidone, etc.) or low temperature solvents (such as liquid nitrogen and liquid ammonia) were adopted during milling aluminum powders with graphene materials. In some cases, organic additives are intentionally incorporated in the powder mixtures to control milling process. These additives (e.g., stearic acid, acrylic acid) easily adsorb on the surfaces of

powder particulates, which would minimize cold welding and prevent agglomeration between impacted particulates. In practice, ultrasonic treatment and surface modification are often carried out ahead of the ball milling process to improve the dispersion of graphene materials. As graphene materials tend to agglomerate into clusters under van der Waals forces, ultrasonic treatment of graphene materials in liquid milling media is essential to break down agglomerates into their constituent forms, and surface modification is helpful to keep these nanofillers apart. Adding organic surfactants is a common method used to disperse graphene materials and keep the solution stable. Surfactants consisting of both a hydrophilic head and hydrophobic group can be physically adsorbed on the graphene nanoflake surface. By introducing repulsive forces or steric hindrance among individual graphene layers, a colloidal suspension yields consequently. Surfactants such as sodium dodecylbenzenesulfonate (SDBS), sodium dodecyl sulfate (SDS), and hexadecyltrimethylammonium bromide (CTAB), and nonionic surfactant, octyl phenol ethoxylate (Triton X-100) are known to be effective in the stabilization of exfoliated graphene nanofillers.^[38] Alternatively, it is also common to use amphiphilic graphene oxide instead of hydrophobic graphene as raw material because the amphiphilic property of graphene oxide makes it easier to disperse in various solvents. After wet ball milling, extra solvents and additives were evaporated or thermally decomposed from the mixtures. In spite of the simplicity and efficiency in graphene dispersion, high-energy milling processes were accused of introducing contamination and defects to graphene materials. Figure 2 presents the Raman spectra of graphene with different milling periods, and the intensity rate between D-band and G-band indicates the integrity disordering and defect density in the graphitic structure.^[39] It is confirmed that ball milling could increase the value of I_D/I_G significantly by introducing defects and disorder to the graphene nanofiller clusters.

Apart from high-energy milling processes, another strategy for improving the dispersion of graphene materials in aluminum matrix is to establish adsorption forces between aluminum particulates and graphene materials molecules.^[29,40] Two approaches were raised based on the adsorption strategy. In the first approach,^[29] surface modification of aluminum particulates was carried out to make their surface properties more compatible with graphene materials. Typical high hydrophilic polymers such as polyvinyl alcohol (PVA) were utilized as the surface modifiers. Substantially, the modified surfaces of aluminum particulates were wrapped by graphene molecules through hydrogen bonding formation. Eventually, the surface modifier was removed by pyrolysis reactions. This approach is remarkably effective in achieving a uniform distribution of graphene materials surrounding the surface of aluminum particulates, as the adsorption capacity of graphene materials is significantly improved. However, it would also bring residual impurities because of incomplete

Fig. 2 Raman spectra of the milled Al6061-2.0 wt.% graphene powder at different milling times and as-received graphene^[39]

pyrolytic removal of surface modifier. To simplify the adsorption processing and avoid unnecessary contamination, a particular electrostatic adsorption approach based on the electrostatic interaction between graphene materials molecules and aluminum particulates was revealed afterward. In this method, graphene materials such as graphene oxides nanofillers were dispersed in an aqueous solution, which was constantly stirred for a period along with the blending of aluminum particulates.^[40] Due to the existence of carboxyl, hydroxyl, and other ionogenic groups, the graphene materials molecules were negatively charged in aqueous solution, whereas the aluminum particulates were positively charged as a result of their surface ionization. The electrostatic attraction between ionized graphene materials molecules and aluminum particulates is effective in their uniform combination.

Consolidating Processes

After dispersing graphene within aluminum particulates homogeneously, an appropriate consolidation process is essential to obtain good graphene-reinforced aluminum matrix nanocomposites with excellent performance. Consolidation process serves to establish good bonding among mixture powders and eliminate the porosity to achieve a full-dense composite.

Pressureless sintering is one of the simplest processes to achieve the densification of graphene-reinforced aluminum matrix nanocomposites, which involves cold compacting graphene/Al mixtures into preforms with unidirectional/isostatic press and sintering the preforms with or without protective atmosphere. The thermal energy applied in sintering drives the densification of the compacted preform as well as the growing of its average grain size. Atom diffusion is the most important sintering mechanism; sufficient temperature (80% the melting point of sintering phase) is

generally required to activate the diffusion kinetic. In the case of aluminum materials, the existing alumina layer surrounding aluminum particles would impede Al atom diffusion. Employing an elevated sintering temperature is a practical option to promote Al sintering; however, a high temperature would result in Al grain coarsening and bring undesired interface reactions in the case of graphene-reinforced aluminum matrix nanocomposites. According to the Hall–Petch relationship, the strength of composites will sharply decline once the grain coarsening occurs. And the formation of Al_4C_3 interfacial phase^[36,41,42] will consume the graphene phase directly and deteriorate the load transfer from matrix to graphene reinforcement. Pressure-assisted sintering is the alternative to achieve a better densification without bringing extra problems. Employing an external pressure during sintering would increase the driving force and kinetics of densification through plastic deformation and creep mechanisms. On the other hand, the applied external pressure does not result in grain growth of aluminum matrix. As the densification rate is enhanced by external pressure, the sintering temperature as well as the sintering time can be reduced, and then grain growth could be suppressed. Various techniques are available in pressure-assisted sintering, such as HP and HIP.

HP takes use of a unidirectional pressure to assist sintering by consolidating powder compact in a die at a moderate temperature with vacuum or protective atmosphere. By improving the heating manner, a new HP technique, so-called spark plasma sintering, has been developed.^[43] The schematic diagram of SPS is given in Fig. 3, the experimental setup is very similar to that of HP. The heating of powder compact is provided by a pulsed current under a pulsed direct current voltage. Generally, a high heating

rate of more than several hundred degrees per minute can be achieved. Compared with traditional methods, the densification process is very fast in SPS, which takes only a few minutes. On the other hand, the grain growth can be limited significantly due to a lower process temperature and shorter process time. SPS is an energy-saving and time-saving method for sintering graphene-reinforced aluminum matrix nanocomposites; besides, the grain coarsening is heavily inhibited because of the low sintering temperature and short sintering duration, which makes it an ideal way for preparation of nanocrystalline metal matrix composite materials.^[44,45] By improving the pressing manner, another different pressure-assisted sintering, so-called hot isostatic pressing, has been developed. HIP is usually carried out after encapsulation of the powder compacts within a container, and pressure is given through compressing an inert gas. Despite the process complexity and requirement for demanding equipment, the properties of metal matrix composite materials achieved by HIP is usually superior.^[46–48] Due to the high isostatic pressure, the required sintering temperature could be greatly reduced by 10%–15%, leading to the fine grains and inhibition of chemical reactions between graphene nanofillers and aluminum matrix, both of which will benefit the performance of composites. What is more, many less pores are left and the homogenization of composites is greatly improved via HIP.

Apart from sintering processes, process of hot rolling or extrusion is also adopted for the preparation of graphene-reinforced aluminum matrix nanocomposites. For instance, S.E. Shin stuffed the mixed powder of few layer graphene and aluminum particulates within a copper tube and hot-rolled it repeatedly.^[8] The hot-rolling

temperature is 500°C, and the copper container was then mechanically removed. The resulting graphene-reinforced aluminum matrix nanocomposites were reported to exhibit dense structure and excellent mechanical properties.

Friction stirring processing (FSP), which is derived from friction stirring welding, is also applied for fabricating graphene-reinforced aluminum matrix nanocomposites.^[49,50] As shown in Fig. 4, intense heat is generated by the friction between rotating shoulder and workpiece to soften the processing zone.^[51] The pin is used for stirring within workpiece to bring intensive plastic deformation and material mixing, which will lead to microstructure densification, homogenization, and refinement in processing zone. FSP is used primarily to fabricate fine-grained superplastic aluminum by Mishra.^[52] In the process for the preparation of graphene-reinforced aluminum matrix nanocomposites, graphene oxide was introduced directly to the surface of the metal matrix in the form of an aqueous colloid by Chi-Hoon Jeon.^[49] Water was supposed to evaporate by the heating from friction, and graphene oxide was thermally reduced, uniformly blended, and incorporated into aluminum matrix during FSP. The results show that the graphene-reinforced aluminum matrix nanocomposites by FSP exhibited a decrease in tensile strength while its elongation was improved.

Besides, electrochemical deposition and melt processing comprising electrodeposition,^[53] electroless deposition,^[54] stirring casting,^[55] melt infiltration,^[56] laser deposition,^[57] and so on were frequently reported to manufacture metal matrix composites. However, electrochemical deposition was more suitable to prepare graphene-reinforced nickel-^[53] or copper-^[58] based composites. Although melt processing is promising to fabricate graphene-reinforced aluminum matrix nanocomposites in large quantities, few report has been presented in this area as a result of the difficulties to disperse graphene and avoid its consumption during melt processing. Nevertheless, economical melt

processing, especially improved stir casting, for graphene-reinforced aluminum matrix nanocomposites is worthy to be developed in the future.

STRUCTURE AND PROPERTIES

Graphene-reinforced aluminum matrix nanocomposites have recently been synthesized by various improved fabrication processes. Then the structure and corresponding performance of graphene-reinforced aluminum matrix nanocomposites fabricated with various powder metallurgy routes have been investigated in the last few years. The results of synthesizing processes and corresponding properties of some recently developed graphene-reinforced aluminum matrix nanocomposites are summarized in Table 1. The structure of nanocomposites is determined by its fabrication process, and the properties of nanocomposites are determined by its structure. Similar to other nanostructured composites, the dispersion of graphene nanoflakes in aluminum matrix and the interfacial bonding strength between graphene and matrix would significantly influence the mechanical properties of graphene-reinforced aluminum matrix nanocomposites. Consolidation of graphene-reinforced aluminum matrix nanocomposites is also critical in achieving excellent mechanical properties. Poorly dispersed graphene or pores from insufficient powder consolidation may act as defect sites and greatly deteriorate the performance of bulk nanocomposites. On the other hand, high processing temperatures to avoid insufficient consolidation may result in unfavorable reactions and generate poor interfacial strength.

Bartolucci and his coworkers^[22] fabricated 0.1 wt.% graphene-reinforced aluminum matrix nanocomposites using powder metallurgy routing. Gas-atomized pure aluminum powders and thermally exfoliated and reduced

Table 1 Fabrication processes and corresponding mechanical properties of some recently developed graphene-reinforced aluminum matrix nanocomposite

Composition	Fabrication processes	Mechanical properties	Research group
0.1 wt.% GR/Al	Ball milling HIP: 375°C, 20 min Hot extrusion: 550°C, 4:1 ratio	Ultimate tensile strength (UTS): 262 MPa, d: 2.6%, Vickers hardness: 99 ± 5 (as-pressed), 84 ± 5 (s-extruded)	Bartolucci et al. ^[22]
0.15 wt.% GR/2024-Al	Ball milling HIP: 480°C, 2 h Hot extrusion: 450°C, 16:1 ratio	0.2% YS: 262 MPa, UTS: 400 MPa, d: 12%	Yan et al. ^[46,47]

graphene plates (Fig. 1) were blended in a powder mixer for 5 min and then milled in a high energy attritor under an argon atmosphere for 1 h. To minimize cold welding and prevent agglomeration during milling, 2 wt.% of stearic acid was utilized as a process control agent. The blends were consolidated via instrumented HIP at around 375°C for 20 min. Subsequently, the consolidated rods were hot extruded at 550°C with an extrusion ratio of 4:1. Figure 5 shows the optical micrographs of polished and etched

aluminum and graphene-reinforced aluminum matrix nanocomposites specimens with 0.1 wt.% graphene addition in the hot extruded condition. The retained structure from powder consolidation and alignment during hot extrusion makes it difficult to measure grain size quantitatively. Compared with pure aluminum, a finer grain structure in the graphene-reinforced aluminum matrix nanocomposites can be observed, which could contribute to the nanocomposites having higher as-pressed hardness values. Despite

Fig. 5 Optical micrographs of extruded 0.1 wt.% graphene-reinforced aluminum matrix nanocomposites (a) and pure Al (b)^[22]

a finer microstructure, the formation of aluminum carbide in the graphene nanocomposites still leads to decreased mechanical properties. The formation of aluminum carbide was confirmed by X-ray diffraction (XRD) patterns of hot extruded graphene nanocomposites (see Fig. 6), which could result from a relatively high extrusion temperature.

Our research group started the investigation on graphene-reinforced aluminum matrix nanocomposites with a similar powder metallurgy fabricating routing.^[46,47] However, compared with Bartolucci's study, a much lower hot extrusion temperature was applied. In our work, typically, gas-atomized Al-Mg-Cu alloys powders and chemically reduced graphene nanoflakes were used as the starting materials. Graphene nanoflakes were ultrasonic dispersed in ethanol for 1 h and ball milled with aluminum alloys powders. Here, stainless steel balls and a stainless steel milling jar were used. The milling was carried out with a ball-to-powder weight ratio of 5:1 and at a speed of 75 r/min for 12 h. Then the mixed slurry was obtained and evaporated at 60°C–80°C for 24 h. Subsequently, the remaining mixtures were consolidated via HIP at 480°C and 110 MPa for 2 h. Finally, the rods of graphene-reinforced aluminum matrix nanocomposites were achieved by hot extrusion at 450°C with an extrusion ratio of 16:1. The extruded rods were heat treated at 495°C for half an hour and then quenched in water. Aluminum carbide was not determined in the produced

graphene-reinforced aluminum matrix nanocomposites according to their XRD patterns (Fig. 7). Conversely, integrated graphene with veiling formed morphology was observed in the TEM images (Fig. 8) of extruded rod of the 0.15 wt.% graphene-reinforced aluminum matrix nanocomposites. Additionally, good bonding interfaces between graphene and aluminum can be achieved, which plays an important role in improving the mechanical performance of nanocomposites. This could be the first report about observing integrated graphene nanoflakes within aluminum matrix, which provides the direct proof on the successful incorporation of graphene without damaging its intrinsic structure through a powder metallurgy routing. By incorporating 0.15 and 0.5 wt% of graphene into Al-Mg-Cu alloys, the tensile strength increases from 373 to 400 MPa and 467 MPa, respectively, and the yielding strength increases from 214 to 262 MPa and 319 MPa separately. What is more, the plasticity of the nanocomposites did not decrease along with nearly 50% improvement in yielding strength. This behavior is quite different from other metal matrix composites and could result from the wrinkled structure of graphene and its excellent interface combination with aluminum matrix. The wrinkled graphene nanoflakes were straightened at the beginning of plastic deformation and then pulled out from the aluminum alloys matrix along with its rupture. This special cooperative deforming mechanism of graphene in aluminum matrix

Fig. 6 XRD of pure aluminum, 1.0 wt.% MWCNT/Al composites, and 0.1 wt.% graphene/Al composites after extrusion^[22]

contributes to the excellent ductility of graphene-reinforced aluminum alloy matrix nanocomposites. The pullout graphene was observed on tensile fracture surfaces of the 0.50 wt.% graphene-reinforced aluminum alloy matrix nanocomposites (Fig. 9).

Recently, Shin and his colleagues in Korea reported their research work on graphene-reinforced aluminum matrix nanocomposites synthesized via hot rolling of ball-milled powder.^[8,60] Graphite flakes with 6–8 nm thickness were primarily mechanically exfoliated by planetary ball milling with a ball-to-powder weight ratio of 15:1 in the present of isopropyl alcohol. The ball milling was intermittent so as to maintain ambient processing temperature, and rotation was carried out at 200 RPM with a total duration of 1 h. The exfoliated graphite flakes were further milled with aluminum powders with 1 wt.% stearic acid, and similarly the rotation was executed intermittently at 100 RPM for 3 h. Exfoliated graphene flakes with a size below 10 microns were observed on the surface of aluminum as showed in Fig. 10a,b where graphene flakes were thin enough to see

clear the morphology of aluminum underneath. Eventually, the mixtures were high energy ball milled in an attritor at 500 RPM for 6 h with argon atmosphere protection. The graphene flakes were supposed to be embedded and dispersed inside aluminum as they were not observed on

aluminum surface by scanning electron microscopy (SEM) even with high magnification (Fig. 10c,d). The consolidation of ball-milled powders was carried out by compacting and hot rolling. The hot rolling was conducted at 500°C with a 12% reduction per pass until obtaining fully dense composite sheet. The exfoliated graphene flakes dispersed within aluminum matrix were confirmed by transmission electron microscopy (TEM) observation, which were slightly wrinkled and aligned along the rolling direction as

shown in Fig. 11. The average layer number of graphene in the nanocomposites was statistically measured to be five atomic layers. The mechanical performance of hot-rolled graphene-reinforced aluminum matrix nanocomposites was testified through tensile experiments. Ball milling contributed to the 160% improvement in yield strength through grain refinement in monolithic aluminum. With 0.7 vol.% graphene reinforcement, yield strength further increased from 262 MPa to 440 MPa, while the ductility greatly decreased from 13% to only 3%. Considering yield strength σ_c , the strengthening efficiency of graphene and Multi-walled carbon nanotube (MWCNT) in aluminum matrix nanocomposites is compared experimentally and theoretically. The $d\sigma_c/dV_{\text{graphene}}$ was calculated experimentally and theoretically to be 26.5 GPa and 24.2 GPa separately, whereas the $d\sigma_c/dV_{\text{MWCNT}}$ was calculated similarly to be 7.5 GPa and 8.5 GPa, respectively. The strengthening efficiency of graphene in aluminum matrix nanocomposites is around three times over MWCNT, which could mainly due to a larger SSA of graphene than MWCNT. The interface between reinforcement and matrix is believed to play an important role in strengthening mechanism.

Wang et al. fabricated graphene-reinforced pure aluminum nanocomposites using a Flake PM routing.^[29] Graphene oxide nanoflakes with a lot of hydroxyl and epoxy groups on the surface were used as the raw material to facilitate the dispersion and form a stable solution. Spherical aluminum particulates were flattened into thin flakes through ball milling to achieve a larger surface area and suitable morphology for adsorption. High hydrophilic polymer PVA was used as the binder to attach graphene oxide nanoflakes to the surface of aluminum flakes. After treated by 3 wt.% PVA aqueous solution, the aluminum flakes were added to deionized water to form a powder slurry. Graphene oxide nanoflakes aqueous dispersion was added drop by drop into aluminum slurry with mechanical stirring, and then mixtures were obtained after filtration. Fine wrinkled rather than smooth morphology was observed on the surface of aluminum flakes by SEM investigation (Fig. 12), which indicated a homogeneous dispersion of Graphene oxide (GO) nanoflakes. Both energy-dispersive spectroscopy (EDS) analysis and Raman spectra measurement confirmed the adsorption of GO nanoflakes by aluminum flakes. The PVA binder was decomposed at 550°C in flowing Ar for 2 h and meanwhile the GO nanoflakes were thermally reduced to graphene sufficiently. The effective transformation of GO to graphene was confirmed by Fourier transform infrared spectroscopy (FTIR) (Fig. 13). After thermal reduction of GO, the characteristic bands of O–H, C=O, and C–O stretching vibration at 3350 cm^{-1} , 1725 cm^{-1} , and 1205 cm^{-1} , respectively, decreased or even disappeared, while a band of vibration from graphitic domains emerged at 1421 cm^{-1} . Substantially the graphene/Al composite powders were compacted into billets and then consolidated by sintering at 580°C for 2 h with argon protection. Hot extrusion at 440°C with an

Fig. 12 (a) SEM image of an Al flake surface with adsorbed GO nanoflakes. (b) SEM image of an Al flake surface without GO nanoflakes. (c) The EDS of the selected area in (a). (d) Raman spectra of GO powder and 0.3 wt.% GO/Al powders^[29]

extrusion ratio of 20:1 was carried out to achieve a dense composite. The mechanical properties of nanocomposites were tested, and graphene contributed 62% improvement in tensile strength from 154 MPa to 249 MPa with only 0.3 wt% incorporation. The enhancement ratio of graphene significantly exceeded that of any other reinforcements, which demonstrates that graphene has a great potential as one of the most ideal reinforcements in aluminum matrix composites. Graphene was believed to enhance the strength through the following three mechanisms: grain size refinement, dislocation strengthening, and stress transfer. On the one hand, the distribution of graphene in aluminum matrix inhibits aluminum grain growth during thermal processing and blocks the motion of the dislocations during plastic deformation. On the other hand, graphene was expected to bear some portion of stress during deformation because of its excellent mechanical properties.

CONCLUSION

Graphene materials exhibit exceptional high elastic modulus and strength, large SSA, and low density as well as high thermal stability. Significantly, attention has been paid to the synthesis and applications of graphene materials due to their remarkable properties by large number of scientists and engineers. Incorporating graphene materials into aluminum matrix for strengthening aluminum composites is one of the applications developed in recent years. Small amounts of graphene nanofillers additions were reported to improve the tensile strength, yielding strength, flexural strength, and hardness of the resulting composites remarkably. The strengthening efficiency of graphene is determined three times higher than MWCNT, as larger surface area would provide more interfacial region. In addition to improving the strength, the incorporation of flexible graphene with aluminum alloys was found to lead to only a small reduction or even an increase in their tensile ductility in some research studies. The mechanical performance of graphene-reinforced aluminum matrix nanocomposites is determined greatly by the properties of the matrix, dispersion of graphene materials, interfacial bonding, and the fabrication processing employed. Ball milling is proven to be an effective and economical dispersion process for achieving homogeneous dispersion of graphene nanofillers in the aluminum matrix, although contamination and damage to graphene nanofillers can hardly be avoided. Slurry adsorption is a recently developed dispersion technology for dispersing functional CNT and graphene in aqueous solutions. It appears to be a feasible and effective process for uniform dispersion of graphene nanofillers in the aluminum matrix without bringing damage or contamination to graphene reinforcements. Consolidation processes with low temperatures are affirmed suitable for graphene-reinforced aluminum matrix nanocomposites to avoid unfavorable interfacial reactions; however, the parameters should be optimized to achieve good interfacial bonding. The effectiveness of load transfer from the aluminum matrix to graphene nanofillers

Fig. 13 (a) Structure of the graphene and GO. (b) FTIR of the GO and reduced GO by rapid heating to 550°C in a flowing Ar atmosphere^[29]

during mechanical deformation is primarily determined by the interfaces. Therefore, good interfacial adhesion is essential to exploit the exceptional mechanical properties of graphene reinforcements.

Based on the rule of mixtures and the super-high strength of single-layer graphene, with a small amount of graphene addition, the strength of graphene-reinforced aluminum matrix nanocomposites will be several times higher than that of Al matrix. All the reported experimental data were much lower than theoretical results so far. The development of graphene-reinforced aluminum matrix nanocomposites is still in its early stage; the processing parameters, microstructure, interfacial reaction, and bonding of the graphene-reinforced aluminum matrix nanocomposites were not yet optimized, leaving much room to further improve their mechanical performance. More research work is needed to explore their physical properties such as the corrosion, electrical, and thermal behaviors in the future. Specific to the structural graphene-reinforced aluminum matrix nanocomposites, theoretical study on the strengthening and toughening mechanism of graphene reinforcement is still not sufficient and large-scale continuous preparation method at low cost (such as casting method) is desired.

Hall–Heroult Process

Gabriela M. Martínez-Cázares

Universidad de Monterrey, San Pedro Garza García, NL, 66238, Mexico

Diego Lozano

Universidad de Monterrey, San Pedro Garza García, NL, 66238, Mexico

Abstract

The principle of electrolysis in the production of primary aluminum has been used for more than 100 years. The Hall–Heroult process is based on the electrochemical reaction of alumina dissolved in cryolite, and the use of large amounts of current to promote the reactions. Aluminum of 99%–99.5% purity can be obtained from this process. The principle, reactions, and the electrolytic cell are briefly addressed in this article.

Keywords: Aluminum; Electrolysis; Hall–Heroult.

INTRODUCTION

Aluminum is obtained from bauxite, which is abundant in tropical areas. However, direct smelting is dangerous and costly since the melting point of bauxite is about 2000°C, this would require enormous amount of energy. An easiest way to obtain molten aluminum by electrolysis was discovered in 1886. Due to this discovery, the price of Aluminum dropped 200 to 1 times, transforming the precious metal into a commodity.^[1]

The electrolysis can be defined as the chemical decomposition of certain substance by passing an electrical current through the substance in a dissolved or molten state. The process needs the presence of a cathode, anode, electrolyte, and electrical current.

The name of the process was given since Paul Heroult in France and Charles Hall in the United States developed at the same time, but independently, a process to produce aluminum metal from the electrolytic reduction of crystalline alumina Al_2O_3 .^[1–4] By passing electric current through a bath of molten cryolite (Na_3AlF_6) with dissolved Al_2O_3 , the reduction of alumina takes place and molten aluminum is deposited at the cathode, where the molten aluminum remains separated under the molten cryolite bath due to its higher specific volume, then it is tapped using a vacuum system.^[5]

This principle is still used in the production of primary aluminum, and it is the largest electrolytic industry in the world. This operation requires high energy consumption and produces high levels of CO_2 emissions. The aluminum obtained by electrolysis has a purity of

99.5%–99.8%.^[6] A general diagram of the process is shown in Fig. 1.

In addition to the high energy high cost is also involved in the handling of raw materials during the production of primary aluminum. For each tonne produced, about 1.95 tonnes of alumina (produced from 4 tonnes of bauxite), 0.5 tonnes of carbon of the anode, and 2.2 Kg of fluoride salts^[7,8] are required.

ELECTROLYTIC CELL

The electrolysis process is carried out in electrolytic cells called pots or Hall–Heroult cells. A pot line has many cells connected in series, and various pot lines can be also connected. The electrical current enters the pot line in one end and it flows from one pot to the next, then it flows to the second pot line to return to the switchyard to close the circuit, see Fig. 2. The approximated dimensions of industrial cells are 10 m long by 4 m wide by 1.2 m high.^[9]

Each cell uses large current at low voltage, thus all pots are connected in series. The cell amperage ranges from 34,000 to 130,000 A. The voltage required for decomposition is 1.7 V; however, 4.7 V are required due to the electrical resistance losses. These losses can be reduced by reducing the anode–cathode distance, but the distance is limited to prevent short-circuiting and because the reoxidation of reduced species is increased.^[6,10] The current in modern pot line can reach up to 300,000 A and can consist of more than 200 cells in series.^[7]

Fig. 1 Primary aluminum production diagram

Fig. 2 Connection of multiple pots

The electrolytic cell consists of a firm and thermally insulated steel bottom lined with carbon blocks, which acts as the cathode; carbon anodes; and a bath of 2%–8% dissolved alumina (Al_2O_3) in molten cryolite (Na_3AlF_6) as the electrolyte, see Fig. 3.

There are two types of anodes, the prebaked anodes and the self-baking anodes or also called the Söderberg anodes, which define the type of cell. The Söderberg anodes are less frequently used due to the carcinogenic emissions

related to their fabrication. In the current industry, the prebaked cells are preferred.

Cathode

The carbon blocks of the cathode are made from a very hard high carbon content coal called anthracite and coal tar pitch. Steel conducting bars are embedded inside the carbon lining to conduct the electrical current (negatively charged). The consumption of the cathode is very less compared with the consumption of the anodes, and could last between 2 and 6 years depending on the operating conditions before they need to be replaced.

Anode

In the prebaked cells, the carbon anodes are suspended on an insulated structure above the cathode, and each cell usually consists of 24 anodes. The anodes weight over a tonne, and they are made from carbon rich coke and a mix of pitch or tar, which are pressed and baked at 1100°C in gas-fired furnaces. After baking and cooling down, copper or aluminum rods are inserted in the anodes in holes that are present prior to casting. These conducting rods are welded or bolted to feed electrical current to the cell, see Fig. 4. The anodes are consumed during the reaction and

Fig. 3 Electrolytic cell with prebaked anodes^[3]

Fig. 4 Rodding of anodes

they have to be replaced at regular intervals. The typical electrical resistivity of the prebaked anodes is $0.005 \Omega\text{cm}$.^[4] During operation, the distance between the anode and the cathode can be adjusted vertically and typically is in the range of 30–60 mm.^[9]

Electrolyte

The electrolysis process takes place in a molten bath consisting mainly cryolite, about 80%, since it is among the few solutions that can dissolve alumina, and also because it decomposes at greater potential and has a lower density than aluminum, making it suitable for the electrolysis process. The solution consists of alumina dissolved in cryolite with an excess of aluminum fluoride.

The cryolite or sodium fluoride, Na_3AlF_6 ($3\text{NaF} \cdot \text{AlF}_3$), has a melting point of 1012°C , but some mixtures of cryolite–alumina containing salts are added to lower the melting point and increase the conductivity such as aluminum fluoride (AlF_3) in the range of 5%–15%, calcium fluoride (CaF_2) in the range of 4%–6% or lithium carbonate (Li_2CO_3) and LiF .^[7,11]

The mole NaF/AlF_3 ratio is called the cryolite ratio, and it is typically maintained in the range of 2–3 in the industry. The mass ratio NaF/AlF_3 is called the bath ratio, and it is half the cryolite ratio. This allows to balance the operating temperature in the range of 940°C – 980°C while increasing current efficiency and neutralize the soda from alumina.

The Al_2O_3 concentration plays a key role during the process and has to be monitored and controlled in a tight range of concentration in order to prevent problems. Low alumina concentration is related to the anode effect, where gas is accumulated and separates the electrolyte from the anodes, promoting the formation of electric arc which decrease the current efficiency and consequently cause other problems. On the other hand, an excess of alumina will form a sludge beneath the metal layer between the

cathode and the molten metal. The typical maximum limit of alumina in the industry is around 8%.^[4]

The alumina added to the bath quickly dissolves and lowers the melting point of the bath. The alumina needs agitation to facilitate its solution and to prevent its accumulation under the metal layer due to its larger specific volume. The specific volume of molten cryolite, molten aluminum, and solid Al_2O_3 are 2.1, 2.28, and 3–4 gr/cm^3 , respectively.

PROCESS

Each cell is set to the operating temperature by lowering the anodes to make contact with the layer of carbon lining on the cathode. The short circuit produces heating when the current is turned on and heats the cell to 950°C . After the cell is heated, the anode is lifted 50 mm above the cathode and the cell is prepared for the addition of the cryolite (electrolyte).

The molten cryolite bath is covered by a thick crust of the frozen alumina; the crust allows the process in the cell to be maintained in thermal balance. At the bottom of the cell, thermal insulation controls the heat losses, while at the walls of the cell, a ledge of frozen electrolyte is formed and sufficient heat loss is necessary to maintain the ledge, which stabilizes the temperature of the bath by thickening when heat input is low and thinning with high heat input.

The alumina is fed from the top through feeders, which are located at the center of the cell between anodes. In the middle of the anodes, there is a crust breaker, which is used when the crust is strong so that gases are not allowed to escape; then the crust breaker will penetrate the crust to allow the gases to escape from the bath and to deliver the fresh alumina, see Fig. 3.

The emissions from the reaction of the carbon-based anodes with oxygen and the emission of perfluorocarbons like CF_4 and C_2F_6 ^[8] from the reaction at the cryolite bath are removed with a fume collector. Table 1 displays the controlled and uncontrolled emissions factors for prebaked cells.^[12]

Table 1 Emissions factors for primary aluminum production in prebaked cells^[12]

Emission factors for prebaked cell process (lb/ton Al produced)			
Emission type	Total particulate	Gaseous fluoride	Particulate fluoride
Uncontrolled	94	24	20
Fugitive	5	1.2	1
Emissions to collector	89	22.8	19
Multiple cyclones	19.6	22.8	4.2
Dry alumina scrubber	1.8	0.2	0.4
Dry electrostatic precipitators plus spray tower	4.5	1.4	3.4
Spray tower	112.8	1.4	3.8
Floating bed scrubber	112.8	0.5	3.8
Coated bag filter dry scrubber	1.8	3.4	0.4
Crossflow packed bed	26.3	6.7	5.6
Cry plus secondary scrubber	0.7	0.4	0.3

Below the cryolite bath, a pool of molten aluminum is formed at the cathode because aluminum has a greater density than the bath and is immiscible in cryolite. The molten metal remains at the bottom until sufficient metal has been accumulated. Depending on the cell design, the molten aluminum is removed periodically by tapping, ladling, or it is siphoned out by vacuum systems. The aluminum layer is 3–25 cm thick, while the electrolyte layer is 15–30 cm.

The smelting process of aluminum takes place at about 900°C and is a continuous process where the pot is kept with molten aluminum to prevent its solidification, which would require an expensive rebuilding process.^[8]

REACTIONS

The electrolysis takes place with the combination of electric current and heat; thus, the dissolved alumina dissociates into its ionic components in the electrolyte. The aluminum ions migrate to the cathode as molten metal. The oxide ions are attracted to the anode and react with carbon to produce carbon dioxide.

The overall reaction of the process is:

There are some reactions that take place in the bath for dissolution of alumina, and also reactions that take place between subproducts at the anode and at the cathode.

In order for electrolysis to occur, the dissociation of alumina is needed. This occurs in the molten cryolite (Na_3AlF_6) which ionizes to $3\text{Na}^+ + \text{AlF}_6^{3-}$. Then alumina is dissolved in cryolite through the following reactions:

The anodic reactions at high alumina concentrations of $\text{Al}_2\text{O}_2\text{F}_4^{2-}$ and $\text{Al}_2\text{O}_2\text{F}_6^{4-}$ are as follows:

while at low alumina concentrations, the reactions are as follows:

At the anode, alumina reacts and produces oxygen that consumes the carbon anodes producing CO_2 . The oxide

ions are attracted to the cathode and react with the carbon anodes. The decomposing anodes are lowered into the bath to maintain the proper distance between the anode and the cathode and to avoid an increase in the current, since there is an increase in the electrical resistance caused by a greater layer of electrolyte between the anode and the cathode. On the other hand, a very short distance between the anode and the cathode may cause short-circuiting if the anode makes contact with the metal layer at the bottom. The anodes are replaced typically after 4 weeks of operation, while the cathodes decompose at much slower rate and they are replaced after 4–5 years. In Fig. 5, a schematic representation of a cell with a new anode and a partially consumed anode is shown. The consumed anode is lowered to maintain the proper distance.

The anodic reaction is as follows:

The oxygen ions accumulate at the anode and react with the carbon to form CO and CO_2 as the following reactions takes place:

In the cathodic reaction, Na combines with F from the aluminum fluorides forming F negative ions, which neutralize the Na positive charge and aluminum as follows:

Fig. 5 Schematic representation of new and consumed anodes

CONCLUSION

The electrolysis of aluminum by the Hall–Heroult process is the most popular process to obtain primary Aluminum from alumina. The alumina is dissolved in cryolite and electric current is passed through the bath producing the reduction reaction. This process consumes high energy and produces a considerable amount of emissions. The electrolytic cells or pots consist basically of the carbon electrodes as the anode, electrolyte (cryolite with alumina bath), and the steel bars as the cathode. The principle of the process is widely accepted and is still used since the 1890s.

Hall–Petch Relationship in Aluminum and Aluminum Alloys

Ronald W. Armstrong

Mechanical Engineering, University of Maryland, College Park, MD, 20742, United States

Abstract

The mechanical properties of aluminum are shown to be of special importance beginning from the early 20th-century production of the material in single crystal and polycrystalline form. Experimental and theoretical researches of the time were concerned with particular influence of polycrystalline microstructure and the presence of crystal (grain) boundaries on both the material strength properties and on relation of those same properties to those for the full range of metal and alloy structures. Now it is well established that a relatively low value of the microstructural stress intensity, k_ϵ , is obtained for aluminum in the generalized Hall–Petch relation for its stress–strain, $\sigma_\epsilon - \epsilon$, behavior depending on the average grain diameter, l , with intercept (friction) stress, $\sigma_{0\epsilon}$, which relation is given as:

$$\sigma_\epsilon = \sigma_{0\epsilon} + k_\epsilon l^{-1/2}$$

With hindsight, taking $\sigma_\epsilon = \sigma_{0\epsilon}$ provided the first connection between single crystal and polycrystalline strength measurements in the pioneering Taylor theory of plasticity proposed for aluminum and other face-centered cubic metals. Later, conventional and ultrafine grain size measurements are shown to verify the fuller H–P dependence. The present account builds onto the early history. A description is given for temperature, strain rate, and alloy-dependent mechanical property measurements. An understanding of the total measurements is described in terms of a dislocation pile-up model description for the relation. Emphasis is given to k_ϵ for pure aluminum and related metals being determined by cross-slip forced at grain boundaries. Particular attention is given to two characteristics of the metal mechanical behavior: (1) very high rate loading deformations leading to shock and *shock-less* isentropic compression experiments and (2) important grain size influences on nanopolycrystalline material behaviors. Additional results are presented on H–P aspects of the material strain ageing, shear banding, ductile fracturing, and fatigue behaviors.

Keywords: Aluminum; Aluminum alloys; Cross-slip; Dislocation pileups; Fatigue; Fracture; Hall–Petch relation; Nanopolycrystals; Shear banding; Z–A relations.

INTRODUCTION

An early assessment of newly determined mechanical property measurements made on the 20th-century face-centered cubic (fcc) metal, aluminum, took place at an important Faraday Society meeting in 1927. Taylor, Polanyi, and Gough, among other leading researchers, presented very different views on whether the presence of grain boundaries in aluminum should directly affect the relationship of single crystal and polycrystalline strength properties. Taylor argued for absence of any direct grain boundary effect,^[1] while Polanyi provided particular evidence that there must be an important influence.^[2] Gough, famous for research on fatigue, reported on torsional straining observations made of mutual grain interferences in testing a relatively large tri-crystal specimen. He concluded that the effect of the grain boundaries was mainly one of “interference” due to the effect of the different

crystal orientations.^[3] Taylor expressed the opinion that slip within an individual crystal was the same, whether it was isolated or bounded by other crystals within a polycrystalline microstructure. The consideration led to a dislocation mechanics description of a parabolic $\sigma_\epsilon - \epsilon$ curve for aluminum and related face-centered cubic metal single crystal deformation curves,^[4] and later, led to the notion that the constraint within mutually deforming (crystal) grains should require five independent deformation systems to operate within the individual grains so as to alleviate an arbitrary difference in the crystal-based strains tied to each grain orientation.^[5] As will be discussed, the analysis resulted in a Taylor orientation factor, m_T , to relate the single crystal resolved shear stress, τ_R , and the unidirectional tensile or compression value of flow stress, σ_ϵ ; that is, $\sigma_\epsilon = m_T \tau_R$. A value of $m_T = 3.08$ was calculated by Taylor. Only quite some years later did Kocks add to the model consideration by pointing to the Taylor requirement

needing a comparative single crystal deformation curve undergoing *multi-slip* on the five requisite slip systems, so that τ_R would be replaced by τ_M .^[6]

Polanyi's objection was expressed as "The interruption [of slip] at the grain boundary constrains the deformation, bringing about a thorough crumpling in the [grain] interior. It is to be expected that this constraint at the boundaries will be most strongly apparent in their immediate neighborhood. This is seen in the extension of a specimen consisting of two [aluminum] crystals, a ridge always forming at the boundary" And elsewhere in discussion at the meeting, Polanyi made the point that "the boundaries of crystals had a distinctly increased resistance against deformation, even if the crystals were of cubic structure. ...". There is modern connection with Polanyi's argument given in a description of "orange peel" effect associated with the surface roughness induced in large grain aluminum materials subjected to substantial plastic deformation.^[7] A compression test result was shown for a 7075-T6 aluminum alloy specimen subjected to large strain after which surface "wrinkling" and macro-cracking started from micro-cracks initiated in the grain boundary "valleys" of the wrinkles, particularly with greater concentration at the equatorial circumference of the bulged specimen. Such "valleys" for the remaining-in-place grain boundaries provide the counterpart of Polanyi's "ridges" on a tensile specimen.

A later update on the consideration of the relationship between single crystal and polycrystalline metal plastic deformation was given by Chalmers in 1950 in another important conference on crystal plasticity.^[8] Taylor's description of five needed slip systems within the individual (crystal) grains was discussed in comparison with the need for taking into account more directly an influence of the material grain boundary properties/effects. The case for higher temperature weakening associated with the presence of grain boundaries was raised. In subsequent years, a number of deformation experiments were designed for application to aluminum bi-crystals "grown" with grain boundaries either parallel^[9] or perpendicular^[10,11] to the tensile axis. There is additional relation in the bi-crystal experiments of Pond and Harrison^[11] to Polanyi's concern for a grain boundary resistance to displacement. Slip band rotations on either side of a grain boundary orthogonal to the tensile axis were shown to cause a sideways displacement of the essentially rigid boundary. Such rotations produced smaller specimen displacements on the crystal side where shorter slip band lengths impinged on the boundary. An important local observation was that the crystal boundary region exhibited smaller plastic strains in each case.^[10,11] A modern aluminum bi-crystal reference involving more complex deformations that were forced to occur within a channel-die geometry has been reported by Zaefferer et al.^[12] Chalmers and Aust presented an important review of model grain boundary structures.^[13]

SUBSTRUCTURE, GRAIN BOUNDARIES, AND SUBGRAINS

Very early recognition of the importance of a polycrystalline microstructure to determining strength properties has been tracked historically to the 18th century.^[14] Description of a model tetrakaidecahedron for an ideal polygonal grain shape exhibiting minimum surface area per unit volume is attributed in the 19th century to Lord Kelvin, as reviewed by Smith.^[15] Such shape consideration may be compared in the top-level view of Fig. 1 to an average grain shape reported last century by Rhines et al. for temperature-assisted grain growth in aluminum.^[16] The grain size is normally specified on a linear intercept basis that has the advantage of specifying the grain surface area per unit volume independent of any shape consideration. Focus on the structure of grain boundaries and dislocation substructure within the grains, particularly for aluminum materials, has been a continuing modern research activity.

Hirsch had described pioneering measurements obtained with a micro-focus x-ray beam technique applied to determination of the dislocation densities in polycrystalline cold-worked aluminum.^[17] In the section on physical interpretation of the results, Hirsch began with the consideration that "During plastic flow the stresses around each grain will be non-uniform owing to the constraints imposed by the neighboring grains." The formation of subgrain boundaries by polygonization of like-sign dislocations was proposed to occur either during cold work or immediately thereafter. The work was followed up by breakthrough observations of individual dislocations in aluminum^[18] by transmission electron microscopy (TEM). Dislocation arrangements in subgrain boundaries and motion of individual dislocations were observed in heavily cold-worked aluminum foils, including observation of dislocation cross-slip. An early TEM report on the structure of high-angle grain boundaries in aluminum bi-crystals was reported by Levy who also

Fig. 1 Grain and subgrain structures in aluminum

traced a bit of the early history in which grain boundaries were described as disordered regions.^[19] Le et al. have reported more recently this century on the development of dislocation substructures generated within individual grains for a sintered aluminum polycrystalline material and subsequently deformed in compression by 20%.^[20]

In Fig. 1, the lower-level images show the traces of subgrain boundary patterns within individual aluminum grains as described in detail in Le et al. using TEM, including measurement of the subgrain boundary misorientation angles that, on the left side, were mostly in the range of 0°–5° and on the right side were of 0°–10°. Both measurements of subgrain misorientations are able to be fully accounted for in terms of crystal dislocations. The experimental observations relate to the consideration that dislocations provide both the vehicle by which plastic deformation is achieved and, when mutually intersected or piling up against subgrain boundary structures or “tangles,” provide significant resistance to continued deformation.^[21] Hong et al. have reported on such considerations for TEM measurements made of subgrain boundary networks produced in rolled aluminum material.^[22]

Other x-ray diffraction measurements have been reported for the effect of a resident dislocation substructure on the strength of aluminum materials, following on from Taylor originally pointing to the same type of x-ray asterism being observed in strained single crystal and polycrystalline material.^[1] Ball reported an inverse square root of subgrain size dependence of the flow stress of aluminum in which the subgrain size was specified *via* micro-focus x-ray diffraction measurements.^[23] Weissmann produced pioneering x-ray topographic images of individual aluminum grain deformations in a design of a modified Debye-Scherrer-type x-ray system.^[24] Hultgren reported on the additive effect of grain and polygonized subgrain boundaries increasing the strength properties of aluminum materials.^[25] Additional hardening associated with an increasing misorientation of the subgrain boundaries was also determined. In a related model description of the strengthening properties associated with refractory metals, Armstrong et al. had proposed the schematic description shown in Fig. 2 for the additive strengthening mechanisms.^[26] In the figure, the dislocations are seen as right-side up or inverted Ts distributed with or without impurity/solute-associated black circles, also with a left-side solute-associated subgrain boundary and a right-side grain boundary region with distributed solute segregation. The subgrain obstacle to slip penetration is weaker than that presented by a grain boundary.

HALL-PETCH MEASUREMENTS FOR ALUMINUM

The eponymous Hall-Petch (H-P) relation, reported for an inverse square root of grain diameter dependence of the yield and cleavage stresses of body-centered cubic (bcc)

Fig. 2 Schematic description of dislocation slip in a polycrystalline metal^[26]

mild steel material,^[27,28] provided what seems at first an unlikely alternative relationship to describe the much weaker grain size dependence of strength properties latterly measured for aluminum materials.^[29] Such later association was expressed in a generalized form of the grain size dependence extended beyond steel and related bcc metals to fcc and hexagonal close-packed (hcp) metals in the form:

$$\sigma_{\epsilon} = m_T \left[\tau_{0\epsilon} + k_{se} l^{-1/2} \right] \quad (1)$$

In Eq. 1, m_T is the earlier-mentioned Taylor orientation factor, $\tau_{0\epsilon}$ is the friction shear stress on dislocations in an average pileup obstructed by a grain boundary requiring generation of a critical value of the microstructural shear stress intensity, k_{se} , for overcoming the boundary resistance. In the work of Armstrong et al.,^[29] a weak H-P dependence for aluminum was compared with a much stronger dependence observed for an aluminum-magnesium alloy, as will be discussed in connection with a large value of k_{se} occurring for yield point behavior.

Comparison of Specimen Size and H-P Grain Size Dependencies

A compilation of single crystal, multi-crystal, and fully polycrystalline H-P yield stress or initial proof stress dependencies measured at ambient temperatures is shown for several relatively pure aluminum materials in Fig. 3.^[30–33] The open-circle measurements, beginning from a single crystal tensile stress measurement on the ordinate axis with $\sigma_{0.01} = 2\tau_{0.01}$, are joined by the dashed curve indicating an increase in flow stress for an increasing number of grains in the specimen cross section.^[32] The so-called specimen size effect is dependent on an increasing constraint between the grains occurring as the number of grains in the specimen cross section builds up and leading to an H-P dependence for fully polycrystalline behavior.^[34] Thus, the inequality was established for an initial proof stress

$$2\tau_R \leq \sigma_{\epsilon} \leq m_T \left[\tau_M + k_{se} l^{-1/2} \right] \quad (2)$$

The two H-P lines shown in Fig. 3 attest to the sensitivity of both $\sigma_{0\epsilon}$ and k_{ϵ} to the presence of solute content

Fig. 3 Single crystal, multi-crystal, and true polycrystalline H–P dependencies for relatively pure aluminum materials^[30–33]

in aluminum that has a relatively large solid solubility of elements compared to other metal systems. The lower filled-circle H–P measurements were obtained for fully polycrystalline flow beginning from the largest grain size points for which larger dimension specimens had been employed to ensure a sufficient number of grains in the specimen cross section, thus giving $m_f k_{se} = k_\epsilon = 1.5 \text{ MPa}\cdot\text{mm}^{1/2}$.^[33] The top-most open-circle points apply for other less pure material measurements obtained as part of a broader investigation of temperature and strain rate effects that are to be discussed.^[34] A value of $k_\epsilon = 2.5 \text{ MPa}\cdot\text{mm}^{1/2}$ is obtained for these data. An early compilation of both σ_{0e} and k_ϵ values has been given for aluminum and for other fcc, bcc, and hexagonal close-packed metals and alloys.^[35] More recent reports on the importance of specimen size effects in differentiating between single crystal and polycrystalline behavior have been reported: for pure aluminum by Kim et al.,^[36] for 1100 aluminum by Kwon et al.,^[37] and for nickel by Keller and Hug.^[38]

A later compilation of H–P measurements for the initial proof or yield stresses of a variety of 98.65% or purer aluminum materials and covering a very large range in grain sizes was assembled by Wyrzykowski and Grabski as shown in Fig. 4.^[39] An evaluation of the H–P slope values (microstructural stress intensities) was found to be in the range $0.3 \leq k_\epsilon \leq 2.1 \text{ MPa}\cdot\text{mm}^{1/2}$ with an average value of $k_\epsilon = 1.3 \text{ MPa}\cdot\text{mm}^{1/2}$. The k_ϵ values are compared with the two values of 1.5 and $2.5 \text{ MPa}\cdot\text{mm}^{1/2}$ obtained from Fig. 1. A substantial range of values of σ_{0e} is seen directly in Fig. 4. Wyrzykowski and Grabski pointed to the importance of texture in accounting for the range in σ_{0e} values and to the misorientation character of the grain boundary structures in determining k_ϵ , thus relating to the observations of Hultgren^[25] whose H–P dependence is marked by the number 9 in Fig. 4. The smallest ‘grain size’ results, marked 18–21 in the figure inset, are for l

taken as the subgrain size including number 19 for the referenced measurements of Ball.^[23] Armstrong had given an earlier comparison of H–P k_ϵ values based on both grain and subgrain sizes.^[40]

Strain, Temperature, and Strain Rate Dependencies

The pioneering measurements made by Carreker and Hibbard^[31] were reported without assessment in terms of the H–P parameters, σ_{0e} and k_ϵ , but nevertheless show on examination decreasing values of both parameters with an increase in temperature, more so in σ_{0e} . A weak strain rate dependence of the flow stress was measured by Carreker and Hibbard. Fujita and Tabata later reported measurements made of H–P yield and flow stress dependences at various ϵ values and at 77, 200, 293, 373, and 473 K.^[41] At 293 K, the yield stress was $k_y = 1.8 \text{ MPa}\cdot\text{mm}^{1/2}$ and found to anomalously decrease with a decrease in temperature. In addition, the post-yield stress H–P dependencies beginning at $\epsilon \approx 0.03$ separated into two linear H–P relations. In a region of larger grain size, $1.3 \leq l^{-1/2} \leq 3.5 \text{ mm}^{-1/2}$, relatively lower σ_{0e} and higher k_ϵ values were measured as compared with a same value of k_ϵ reported both for the yield stress and flow stress at smaller grain sizes up to $l^{-1/2} \leq 5.5 \text{ mm}^{-1/2}$. Very likely, as will be seen, the reduced strain hardening that is reflected in the larger grain size flow stresses should be attributed to an influence of texture. Such results would be consistent with the general observation of k_ϵ being relatively larger when a well-defined yield point is observed but then to be followed by a relatively constant k_ϵ value for the flow stress dependence.

Hall–Petch dependencies have been measured also for the complete ambient temperature stress–strain behaviors of pure aluminum by Hansen.^[33,42] Figure 5 shows the progressive H–P flow stress dependencies at a number of increasing tensile true strain values. The H–P dependence

Fig. 4 A compilation of H-P dependencies reported for relatively pure aluminum materials^[39]

Fig. 5 An H-P dependence for the stress-strain behavior of 99.99% aluminum^[33]

shown at $\epsilon=0.01$ is the same result shown in Fig. 3. Hansen importantly compared the $\sigma_{0\epsilon}$ dependence on ϵ with the Taylor prediction of a parabolic $\sigma_{\epsilon}-\epsilon$ dependence and with a single crystal $m_T\tau_M-\epsilon$ measurement for a crystal with^[111] tensile axis orientation to represent Kocks' multi-slip orientation.^[6] A satisfactory near-parabolic strain dependence was found but, somewhat surprisingly, a better match was found with a lower Sachs orientation factor, $m_s=2.24$, previously determined for activation, on average, of the so-called Schmid orientation factor for operation of a single fcc slip system over the full range of crystal orientations. The comparison could be interpreted as well to indicate that the average polycrystal grain does not experience strain hardening to the same extent as occurs for a^[111] tensile axis single crystal. Also, Hansen made a comparison of the aluminum H-P dependence with a stronger one measured for copper,^[43] as also will be compared here in later discussion.

Al-Haidary et al. had obtained very comparable tensile results to those of Hansen at ambient temperature for both

a super-pure 99.98% and commercial 99.2% material and reported additional measurements both at higher temperatures of 200°C and 400°C^[44] and at a lower temperature of 77 K.^[45] Except for a very low H-P dependence established for a proportional limit stress of $\sigma_0 \approx 3$ MPa and $k_0 \approx 0.7$ MPa·mm^{1/2}, the $\sigma_{0.02}$ and higher flow stresses again gave the same $k \approx 2$ to 2.5 MPa·mm^{1/2} increasing with plastic strain to $\epsilon=0.20$ for the purer material. Comparison was made also with the measurements made of a stronger H-P dependence for an aluminum-2.25% magnesium alloy, following on from the same comparison made between the Carreker and Hibbard aluminum measurements obtained at $\epsilon=0.05$ and yield point behavior for an aluminum-3.5% magnesium alloy in reference.^[29] Al-Haidary et al. provided near-parabolic curves for the $\sigma_{0\epsilon}$ dependencies of all three materials at ambient temperature and 200°C and gave an interpretation of the results in terms of the dislocation density, ρ , that may be tracked to the original theory of Taylor^[4] and expectation of a parabolic $\sigma_{\epsilon}-\epsilon$ curve but

with σ_{0e} replacing σ_e .^[46] The addition of the $k_e l^{-1/2}$ term provided evidence that slip transmission across grain boundaries continued to be required during plastic straining. At higher temperatures, evidence was provided for dislocation annihilation occurring and, at lower temperatures, transition occurred to a linear dependence of σ_e on ρ and subsequent hardening due to the difficulty of cross-slip. Ogilvie and Boas had first reported cross-slip occurring in aluminum at the time of its originally being described via surface slip step height observations made on deformed α -brass by Maddin et al.^[47]

Dorn has reported on interpretation of the low temperature deformation properties of aluminum and related metals and alloys in terms of thermally activated dislocation migration and including, among a number of issues, characterizations of dislocation intersections, solute strain centers, and cross-slip.^[48] Such important influence of temperature (and strain rate) enters largely into the σ_{0e} dependence that has been elaborated also on a dislocation mechanics basis by Zerilli and Armstrong^[49,50] in the so-called Z–A relations:

$$\sigma_e = \sigma_{0Ge} + B \exp[-\beta T] + B_0 [\varepsilon_r (1 - \exp\{-\varepsilon / \varepsilon_r\})] \exp[-\alpha T] + k_e l^{-1/2} \quad (3)$$

In Eq. 3, σ_{0Ge} is an athermal stress dependent on the dislocation density, subgrain structure, and solute, and B , β , B_0 , ε_r , and α are experimental constants that are physically based on dislocation mechanics. The second and third terms on the right side of the equation are derived from a thermal activation influence, $\sigma_{The} = \sigma_e - [\sigma_{0Ge} + k_e l^{-1/2}]$, on the material yield stress and strain hardening, respectively. Equation 3 is expressed in a general form potentially applicable to both fcc and bcc metals and alloys; some hcp metals, such as magnesium, zinc, and cadmium, follow an fcc-like behavior while others, such as alpha-titanium, zirconium, and hafnium, follow a bcc-like behavior. The strain rate dependence, $d\varepsilon/dt$, is obtained from the (β, α) parameters that follow a weaker dependence:

$$(\beta, \alpha) = (\beta_0, \alpha_0) - (\beta_1, \alpha_1) \ln(d\varepsilon / dt) \quad (4)$$

The first three terms on the right side of Eq. 3 are normally combined in σ_{0e} . In contrast to the bcc case, for which the temperature and strain rate dependence is in the (second term) yield stress, these dependencies for fcc metals are principally in the strain-hardening. As a consequence, $B=0=\beta_0=\beta_1$, thus leading to the simplified fcc relation:

$$\sigma_e = \sigma_{0Ge} + B_0 [\varepsilon_r (1 - \exp\{-\varepsilon / \varepsilon_r\})] \exp[-\alpha T] + k_e l^{-1/2} \quad (5)$$

The second term on the right side takes account of dislocation annihilation, as described by Al-Haidary et al., and of dynamic recovery that leads to a lesser increase in dislocation density, ρ , than described in the Taylor model.^[50] At small strains, the term approximates to the

Taylor parabolic $\varepsilon^{1/2}$ dependence. Equation 5 has been used to describe extensive measurements reported for copper materials.^[49] Zerilli and Armstrong had given an estimation of several of the Z–A temperature parameters for aluminum.^[51] Other constants have been given for AA7075-T6 material^[52] and for a modified Z–A relationship.^[53] The weaker strain rate dependence indicated in Eq. 4 increases for very high rate loading in shock impact tests and for comparable strain rates achieved in *shock-less* isentropic compression tests.

Shock and Shock-less Isentropic Compression Experiments

The Z–A equations were developed principally to describe high-rate deformations such as impact and leading to shock loading and equivalent strain rates in *shock-less* isentropic compression experiments (ICEs). Huang, Asay, and colleagues have investigated such conditions for ultrapure aluminum (99.9998%) and for various aluminum alloys including polycrystalline and single crystals.^[54–56] Yield stress measurements as high as 90 GPa were reported but without indication of H–P dependence.^[54] Follow-up comparison in tests on single crystal and polycrystal material confirmed the lack of H–P dependence.^[55] Additional high-pressure measurements on aluminum under quasi-isentropic compression generated higher yield stresses.^[56]

Armstrong et al. have reported on both shock and ICE types of very high rate loading and pointed to the different considerations of dislocation generation being important at a propagating shock front as compared with dislocation drag resistance controlling migration of the resident dislocation density in shock-less isentropic compression.^[57] Experimental results on Armco iron and copper were analyzed. An H–P dependence was determined for the shock-induced Hugoniot elastic limit stress, σ_{HEL} , determined by deformation twinning for Armco iron. The subsequent value of σ_e , found to be independent of grain size, was explained in terms of the plastic deformation being necessarily accommodated at the much smaller nanoscale points all along the propagating shock front. For equivalent strain rates reached in shock-less ICEs, a different situation occurs for the uniformly rising compressive stress driving the resident dislocation population at such extreme velocity as to be retarded only by the crystal lattice determined dislocation drag. Higher stresses are required.

Figure 6 shows experimental measurements and predictions obtained on aluminum materials.^[31,57–60] The previously mentioned strain rate-dependent results obtained by Carreker and Hibbard are superposed on the abscissa scale at the lowest strain rates. Močko et al. reported split-Hopkinson pressure bar results obtained on commercial AA 7075-T6 material for which the strain rate-dependent $\Delta\sigma_e$ measurements are plotted in Fig. 6.^[58] Swegle and Grady had reported pioneering measurements

Fig. 6 Strain rate dependence of shock-induced plasticity

on aluminum material that followed the indicated power law relationship drawn in the figure.^[59] The highest stress results by Crowhurst et al.^[60] have been fitted to a linear dependence predicted as a limiting case of the Z-A analysis.^[57] Malygin et al. have provided a dislocation model description of shock wave results obtained on aluminum and related materials.^[61] Gurrutxaga-Lerma et al.^[62] have reported elastodynamic model calculations of the strain rate dependence leading to homogeneous dislocation generation in aluminum.

H-P DISLOCATION PILE-UP MODEL

Both Hall and Petch attributed the inverse square root of grain size dependence exhibited for the yield and cleavage strength measurements made for their steel materials to the dislocation pile-up model proposed at about the same time by Eshelby et al.^[63] In the review by Armstrong,^[35] a value of $k = 23.4 \text{ MPa}\cdot\text{mm}^{1/2}$ was reported for the pronounced lower yield point behavior of mild steel at ambient temperature. A lesser $k_{10} = 12.4 \text{ MPa}\cdot\text{mm}^{1/2}$ was determined for the H-P flow stress dependence, thus indicating by the reduction in value that a high k_{lyp} is associated with a pronounced lower yield point stress determined by carbon locking of dislocations in the grain boundary regions as depicted in Fig. 2. Zener had proposed earlier that such pileups, analogously associated with a model of a shear crack impinging on a grain boundary, were responsible for the yield stress dependence on reciprocal square root of grain size of the brass material^[64] and for the mechanism of cleavage fracturing of steel.^[65] Li and Chou produced a seminal description of dislocation pile-up characteristics.^[66] Armstrong has given a later review of the dislocation pile-up model equations for the H-P dependence.^[67]

Analogous Pile-Up/Shear Crack Description

In the pile-up model description, k_{se} is described as a microstructural shear stress intensity, analogous to the macroscopic stress intensity specified in the fracture mechanics of pre-cracked materials.^[68] Figure 7 illustrates an example connection between the H-P calculations for a single-ended, double ended, and circular pile-up geometry and the counterpart fracture mechanics equations for an edge crack, internal crack, and circular crack geometry. In the figure, $r_0 \approx b$ is a dislocation core radius. At small grain sizes or crack sizes, the figure shows that there is divergence from a continuum description of the crack size dependence as compared with the discontinuous pile-up equation descriptions that are quantized in terms of b or r_0 . As will be seen, such consideration becomes important at the limiting strength properties to be described for nanoscale grain size material.

Far lesser k_e values are measured for plastic yielding, as expected, compared with the cleavage $k_c \approx 100 \text{ MPa}\cdot\text{mm}^{1/2}$ obtained for the low temperature fracturing of iron and steel materials. For general yielding and subsequent plastic flow, the pile-up model for an ideal slip band provides for evaluation of $k_e = m_T k_{se}$ in terms of the local shear stress, τ_c , acting on the lead dislocation in a pileup,^[30] and is given as follows:

$$k_e = m_T \left[\pi m_s G b \tau_c / 2 \alpha' \right]^{1/2} \quad (6)$$

In Eq. 6, m_T and m_s are the Taylor and Sachs orientation factors mentioned above, G is the elastic shear modulus, b is the dislocation Burgers vector, and $\alpha' = 2(1-\nu)/(2-\nu) \approx 0.8$ is an average factor for a screw or edge dislocation character. On this basis, then, the H-P pile-up model description leads to two shear stresses controlling polycrystalline plasticity: τ_{0e} , for the average “friction” shear stress for dislocation movement within the grain volumes, and τ_c , for the local stress gauging the obstacle resistance to transmission of plastic flow across the grain boundary. Two reasons for k_e being relatively large are τ_c is higher for the yield point associated “dislocation locking” in the grain boundary region, as indicated schematically in Fig. 2,^[29,69] and for the combined reasons of m_T , m_s , and τ_c being large for secondary slip or twinning systems to operate in the grain boundary regions. The former effect is best illustrated by steel for which the H-P relation was initially established. A k_{HP} dependence on carbon segregation at grain boundaries, as in Fig. 2, has been recently reported even in the fcc case of a high-manganese austenitic steel.^[70] The latter effect is particularly important for hcp metals and alloys that generally show intermediate k_e values between those of bcc and fcc metals.^[29,71] Important influence of texture on the H-P k_e values has been reported for magnesium alloy materials by Yuan et al.^[72] and by Wang and Choo.^[73]

Fig. 7 Comparison of dislocation pileup and crack size predictions^[67]

Aluminum H–P k_ϵ Determined by Cross-Slip

The importance of (post-Taylor) cross-slip to understanding the deformation and strain hardening behaviors of fcc metals led to the notion that cross-slip could be responsible for determining the value of k_ϵ in pure fcc metals,^[40] especially because of association between the low k_ϵ value for aluminum and its ease of cross-slip. Absence of easy glide and early onset of cross-slip in an aluminum single crystal allowed Taylor to match the deformation curves of single crystal and polycrystalline aluminum. Bell provided a later compilation of cross-slip shear stresses, τ_{III} , in aluminum and in other fcc single crystal deformation results relating to the fit of Taylor-type parabolic strain hardening.^[74] A critical review of the important cross-slip deformation mechanism associated with strain rate effect, hardening, recovery, and microstructural evolution has been given by Püschl.^[75] Alankar et al. have incorporated the mechanism into a model for the development of dislocation densities in single crystals.^[76]

Figure 8 provides a schematic description of cross-slip occurring in the aluminum bi-crystal experiments of Clark and Chalmers.^[9,77] Cross-slip of dislocations at the pile-up tip is proposed to establish a limit on the critical value of τ_c specified in Eq. 6. Of course, $\tau_{III} > \tau_{0e}$ for most single crystal test orientations.

An early comparison^[40] had been made for aluminum and copper of similar temperature dependencies for their cross-slip shear stresses, τ_{III} ,^[74,78] and k_ϵ^2 values.^[41,79] compiled from reported data. Likewise, similar strain rate dependencies were established for copper τ_{III} and k_ϵ^2 values.^[80] Such predictions had been established earlier for H–P measurements reported for (hcp) magnesium material in which σ_{0e} was shown to follow the same temperature dependence as that for the basal slip-resolved shear stress, $\tau_{(0001)<11-20>}$, and k_ϵ^2 was shown to follow the same

temperature dependence as for the resolved shear stress for the prism slip system, $\tau_{\{10-10\}<11-20>}$.^[81] More recently, the prediction of ambient temperature values of k_ϵ determined from Eq. 6 has been compared with experimental measurements. Table 1 provides such comparison for aluminum,^[33] nickel,^[82] copper,^[43] and lead^[83] materials. The experimental k_ϵ values compare very favorably with those tabulated by Hansen.^[84]

H–P APPLICATION TO ALUMINUM ALLOYS

An important review of the early 20th-century development of aluminum alloy technology was given by Dean^[85] in an article giving great credit to very relevant metallurgical contributions of Zay Jeffries; see also, for example, the pioneering reference to Jeffries on grain size effects in metals.^[86] Dean described pioneering contributions made by Jeffries on aluminum alloy casting technology, particularly Al–Si and Al–Si–Cu alloy developments; aluminum alloy thermal expansion properties; beneficial microstructural refinement *via* high solidification rates; heat treatment for solid solution strengthening and “aging” for atomic clustering/precipitation strengthening; and aluminum alloy development for forging operations. Interesting connections on the importance of thermal expansivity in aluminum alloy developments may be seen in reported measurements of local plasticity produced by cyclic thermal straining of the Al–Si alloy and other composite materials.^[87,88] A recent report has been given by Czerwinski et al. on high temperature Al–Si–Cu–Mg base alloys with Zr, V, and Ti micro-additions successfully developed for automotive power trains.^[89]

Figure 9 shows the application by Erginer and Gurland of the H–P model description to yield stress measurements made for Al–Si alloy materials in which

Fig. 8 Model for cross-slip in an aluminum bi-crystal deformation experiment^[9,76]

Table 1 Comparison of H-P predicted and experimental k_e values

Metal	Shear modulus (GPa)	Burgers vector (nm)	τ_m (MPa)	Theoretical k_e (MPa·mm ^{1/2})	Experimental k_e (MPa·mm ^{1/2})
Al	25	0.29	4.5	1.2	1.5
Ni	62	0.25	17	3.3	4.9
Cu	30.5	0.256	29	3.1	5.0
Pb	4.8	0.35	1.6	0.33	0.43

the two-phase (intercept) mean free path length, λ , has been substituted for the average grain diameter, l .^[90] The grain size determined H-P results of Carreker and Hibbard^[31] and specimen size affected results of Fleischer and Hosford,^[32] shown in Fig. 3, are plotted near to the origin of the current figure that also indicates thereby a same value of $k_e \approx 2.5$ MPa·mm^{1/2}. Liu and Gurland had indicated the same type of result for higher carbon spheroidized steel materials.^[91] Morrison and Leslie had demonstrated an analogous-type result for lower carbon steel materials.^[92] Thus, one aspect of alloy strengthening caused by precipitates is to effectively refine the microstructural scale. Earlier, Ansell and Lenel had proposed an inverse square root particle spacing dependence for the yield strength of dispersion strengthened, sintered aluminum powder material.^[93]

H-P for Solid Solution Strengthened Alloys

Suzuki and Nakanishi reported H-P measurements for Cu-Al and Cu-Ni alloys^[94] and then presented a detailed dislocation pile-up model description for the H-P dependence of the yield stress for fcc alloy materials.^[95] Measurements of greater k_e values for the two alloys and also for Cu-Zn materials were interpreted in terms of the alloy solute segregating in the grain boundary region analogous to the situation for carbon in steel, see Fig. 2. Very interestingly, a smallest increase in k_e occurred for the Cu-Ni system for which nearly the same k_e values are measured for each one of the pure materials, see Table 1. Mention was made of the temperature dependence for the Cu-Al k_e being the same as that for copper; this relating to the mentioned account^[79] of k_e^2 following that for the

Hall-Petch-Hypocentric
Al-Fe

Fig. 9 Extended H-P application to yield strength of Al-Si alloy materials^[90]

Fig. 10 Compiled H-P dependencies for Al-Mg alloys^[96]

cross-slip shear stress, τ_{III} . Other direct application of an H-P description to yield stress measurements made on several Al-Mg solid solution alloys is shown in the compiled results of Fig. 10^[96] including the pure aluminum result and H-P temperature dependence for Al-2-25

Mg.^[45] Results on Al-Li and Cu-Zn (brass) alloy materials were also presented.^[96]

Other H-P connection has been made for textured Al-Li 2090-T8E41 alloy relating to its very significant anisotropic plastic deformation and cracking behavior associated with both laminated grains exhibiting a crystallographic texture.^[77] The material is a candidate for structural applications in the aerospace industry. The surface structure of a residual macro-indentation was employed to demonstrate the plastic anisotropy of the elongated grain structure. Microscopic grain boundary protrusions into the residual circumferential crater were taken to demonstrate grain size strengthening in an analogous manner to that described by Polanyi.^[2] Delamination-type cracking was described for dislocation pile-up reactions based on the material having an ideal copper or brass texture. A later report has been made by Tayon et al. relating the delamination cracking to orientation variants of a brass texture.^[97] The fracturing was attributed to "a lack of slip accommodation across the [grain] boundary, which promotes significantly higher deformation in one grain and, and stress concentrations that promote delamination ..."

Serrated Plastic Flow

The strong grain size dependence associated with serrated plastic flow in metal alloys has been reviewed by Antolovich and Armstrong.^[98] Original deformation curves reported for an Al-Cu-Mn alloy in 1923 by Portevin and Le Chatelier^[99] and in 1949 on a commercial aluminum material by McReynolds^[100] were reproduced in the review. Cottrell had explained the PLC behavior in terms of sequential

Fig. 11 H-P dependencies for Al 5086 alloy material^[102]

dynamic interaction of diffusing substitutional solute with deformation-induced dislocation migration^[101] but, until the present time, little attention has been given to the importance of a substantial grain size dependence of the behavior relating to influence of H-P consideration. There is an important strengthening effect at lower strain rate because of the analogous behavior to strain aging observed for carbon in steel. Wagenhofer et al. investigated the strain rate and grain size-dependent behavior for the commercial Al-4wt% Mg alloy 5086, also containing 0.4wt% Mn and 0.15wt% Cr.^[102] Figure 11 shows a comparison of the higher flow stress measurements made on as-received material in an H-32 cold-worked and proprietary recovery treatment as compared with the material in a (lower stress) fully annealed condition and with Al-4.5 Mg results and pure aluminum material. Serrated flow was observed, for example, at a strain rate of 10^{-3} s^{-1} and an absence of serrations was observed for a lower flow stress at a higher strain rate 0.36 s^{-1} . The increased strengthening at lower strain rate was compared with very high-rate loading measurements and to a Z-A model description of them. The PLC behavior is a particularly important research topic in current investigations of nickel superalloy materials.^[103]

ULTRAFINE TO NANOSCALE GRAIN SIZES

Extension of the conventional H-P measurements to nanoscale grain sizes of steel materials gave an indication that increases of yield and fracture stresses would occur by

an order of magnitude in the $k_{\epsilon} l^{-1/2}$ term; see Table 1 in the work of Armstrong.^[104] An H-P dependence was demonstrated for nanocrystalline aluminum by Bonetti et al.^[105] Mukai and Huguishi reported ductility enhancement measured for an Al-14 wt%-14wt% Mn alloy that followed an H-P dependence and was produced by crystallization of amorphous powders by hot extrusion.^[106] Hokka et al. have reported high-rate torsion results for ultrafine-grained 1070 aluminum material^[107] and Khan et al. demonstrated strain rate-dependent plasticity for nanocrystalline aluminum in dynamic loading tests.^[108] The combined issues of structural morphology, boundary spacing, boundary misorientations, and dislocation density were described for nanostructured aluminum by Huang et al.^[109] Bazarnik et al. reported H-P behavior for an Al-5Mg alloy processed by the method of high-pressure torsion.^[110]

Meyers et al. had produced an earlier comprehensive review of mechanical properties for nanocrystalline materials.^[111] Li edited an important book on the topic.^[112] Armstrong produced a recent review article.^[113] Figure 12 shows a comparison of conventional and nanoscale H-P results plotted on a log/log scale for aluminum, copper, and nickel materials. On such log/log basis, a relatively constant value of $\sigma_{\epsilon} = \sigma_{0e}$ is approached at large grain sizes and a linear slope of $-1/2$ is approached at very small grain sizes. In Fig. 12, the conventional grain size (open symbol) measurements have been referenced already for aluminum,^[31] copper,^[43] and nickel.^[38] The nickel results, shown at a relatively larger strain of $\epsilon=0.14$ with accompanying $k_{.14}=2.15 \text{ MPa}\cdot\text{mm}^{1/2}$, had been achieved after an initial value of $k_{.002}=5.17 \text{ MPa}\cdot\text{mm}^{1/2}$ was measured. The nickel measurements show an essentially constant value of $k_{\epsilon} \approx 5 \text{ MPa}\cdot\text{mm}^{1/2}$,^[114] very near to the same value as obtained for copper,^[43] see Table 1. The reason for the same initial k_{ϵ} values is attributed to the product, $G\tau_c = G\tau_{III}$ in Eq. 6, thus compensating for a factor of two increase in G for nickel by a reduction of approximately one-half in τ_{III} .

The ultrafine grain size measurements for aluminum, copper, and nickel materials were compiled from results reported, respectively, by Tsuji et al.,^[115] Lu, et al.,^[116] and Torrents et al.^[117] In Fig. 12, the finer grain size measurements for aluminum showed a relatively larger $k_{\epsilon} \approx 3.5 \text{ MPa}\cdot\text{mm}^{1/2}$ at larger grain size then increasing to $\sim 4.5 \text{ MPa}\cdot\text{mm}^{1/2}$ at smaller grain sizes in which a significant yield point behavior was also observed. Such larger k_{ϵ} associated with yield point behavior relates to the earlier-mentioned results for austenitic steel.^[70] The transition to the stronger grain size dependence occurred also at the point of the yield stress becoming equal to the ultimate tensile stress. The yield stresses for the ultrafine grain size measurements are shown to increase by an order of magnitude or more for aluminum and copper, and this is also true for nickel when compared on a yield stress basis. Recent report has been of precipitate and grain boundary influences on strength levels reached above 1.0 GPa and plastic stability of sub-micron aluminum micro-pillars.^[118]

Fig. 12 Conventional and nanoscale H-P results for Al, Cu, and Ni^[113]

Thermal Activation in $k\epsilon$

The value of τ_c in Eq. 6 provides for the possibility of thermal dependence in accordance with the Z-A description given in Eqs. 3–5, with proviso that τ_c is not too large.^[83] The k_ϵ values have been demonstrated to be thermally activated, first, for the hcp metals^[119,120] and then for fcc metals.^[40] As a consequence, the shear strain rate sensitivity parameter, $v^* = k_B T [\partial \ln(d\gamma/dt) / \partial \ln \tau_{Thc}]_T$, with k_B being Boltzmann's constant, takes on an H-P-type grain size dependence from Eqs. 3 and 6 and is given by the relationship

$$(1/v^*) = (1/v_0^*) + (k_\epsilon / 2m_\tau \tau_c v_c^*) l^{-1/2} \quad (7)$$

In Eq. 7, v_0^* is the activation volume determined from strain rate influence on σ_{0e} and the H-P dependence follows from the thermal product, $\tau_{Thc} v_c^*$ being constant^[40,121] and so long as the athermal component of τ_c , that is τ_{GC} , is not too large. Figure 13 shows connection of conventional grain size nickel measurements of Narutani and Takamura^[114] made by Armstrong and Rodriguez^[122] to a combination of smaller grain size measurements for copper and nickel materials compiled by Asaro and Suresh^[123] and, also, with mixed-in nickel measurements reported by Weng,^[124] and with copper measurements reported by Lu et al.^[116] for nano-twinned material taking the twin spacing, λ , as the effective grain size. The two solid Eq. 7 curves are predicted for 195 and 300 K.^[122]

Similar strain rate-dependent nanoindentation hardness measurements made for conventional and ultrafine grain size Al 99.5 material, as those shown on the right side of Fig. 13, were obtained by May et al.,^[125] as reported by Meyers et al.^[111] The strain rate sensitivity measurements in this case were reported in terms of the parameter, $m = [\partial \ln(d\epsilon/dt) / (\partial \ln \sigma)]_T$. A constant value of m was found over a range of strain rate for both grain sizes that, for the ultrafine grain size material, was from 10^{-3} to 1.0 s^{-1} . With the hardness, $H \approx 3\sigma_e$, a value of v^* is obtained as

$$v^* = 3k_B T / mH \quad (8)$$

Fig. 13 A reciprocal activation volume dependence for Cu, Ni, and Al materials

On such a basis, v^* for the conventional grain size material gave relatively constant higher values in the range ~ 80 to $\sim 70 \text{ b}^3$ as compared with the ultrafine grain size material giving a smaller value of v^* decreasing with increasing strain rate from ~ 11 to $\sim 8 \text{ b}^3$, in both cases decreasing with increasing strain rate. The trend of the aluminum v^* values are consistent with those shown for copper in Fig. 13. Choi et al. also have reported reduced v^* measurements for hot-extrusion of ball-milled 99.5 aluminum material in progressing from conventional to nanoscale grain sizes as shown in Fig. 13.^[126]

Grain Size Weakening

At the smallest λ values shown in Fig. 13, a reversed H-P dependence was reported for σ by Lu et al.^[116] as indicated in the top-left corner of the figure and accounted for in terms of constitutive equation behavior at higher temperatures.^[68] For this case, which behavior is generally observed for $l \lesssim 20 \text{ nm}$, there is grain size weakening similar to that observed at very high temperatures of grain boundary shearing and diffusive deformations occurring more easily than transgranular slip or twinning.^[86,127] The weakening in Fig. 13, despite showing a size dependence able to be accounted for in terms of normal high-temperature weakening, has been attributed specifically to twin-associated dislocation nucleation.^[128] Because of stacking fault consideration, such twinning can only be produced in aluminum, for example, in sputtered material.^[129]

Balasubramanian and Langdon had reported creep-connected superplastic flow for an equal-channel angular pressed (ECAPed) sub-micrometer Al-Mg-Sc alloy material for which grain boundary sliding was proposed to be accommodated by intragranular flow of dislocations.^[130] The same authors have produced a more recent review covering superplastic flow observed for a compilation of aluminum- and magnesium-based alloys as well demonstrating appreciable Hall-Petch-based strengthening at nanoscale grain sizes.^[131] Presumably, for the weakening

aspect of such limiting nanoscale material, the H-P-induced very high stress state brings into play localized shear deformations within the grain boundaries. Pande and Cooper have provided an important review of the limiting transition to nanoscale weakening behavior.^[132] Mompiau et al. have provided important *in situ* TEM tensile test observations of intergranular dislocation motion in the grain boundary plane of aluminum thin film material and provided comparison with their own measurements of transgranular plasticity.^[133] Padmanabhan et al. have reported on their own model description of grain/interphase boundary sliding as applied to reported measurements of an inverse H-P effect in Al-Cu-Fe nanoquasicrystalline alloy and nanocrystalline Zn and Ni materials, including the prediction of superplastic flow.^[134] Kong and Fang have produced an important review of grain boundary relaxation measurements first observed in internal friction measurements made on polycrystalline aluminum at above ambient temperatures and now including vertical bi-crystal boundaries, as in Fig. 8, along with limited results reported thus far on ultrafine grain size materials.^[135]

TENSILE PLASTIC INSTABILITY, FRACTURING, AND FATIGUE

Important research results have been obtained on aluminum materials that again serve to elucidate a similar range in the broader aspect of material properties including topics of tensile instability, shear banding, ductile fracturing, and fatigue behavior. Because of its low H-P microstructural stress intensity, k_e value, aluminum doesn't show any remarkable tensile instability behavior other than providing, in line with normal fcc-type constitutive behavior, a greater uniform true strain to maximum load at greater strain rate^[136] and a minor susceptibility to shear banding behavior.^[137]

Tensile Instability/Fracturing

Figure 14 shows an important comparison of H-P yield stress measurements (open triangles and circles) and true stress at maximum load values (closed circles) for accumulative roll-bonded (ARB) and annealed high-purity aluminum material able to be obtained from very complete measurements reported by Kamikawa et al.^[138] The larger grain size, open triangle points were obtained for cold-rolled and annealed material. The smaller grain size, paired circle A, B, C, and D points were associated with significant H-P strengthening from the outset of straining but with appreciably reduced uniform strain leading to rapid onset of plastic instability, compared to the larger grain size points E and F that showed extended strain hardening until reaching the plastic instability stress.

Basinski had produced a pioneering analysis of tensile instability as related to the onset of shear banding in pure and commercial aluminum materials tested at 4.2 K.^[139]

Fig. 14 Yield and maximum true stress for accumulative roll-bonded (ARB) Al

No account was made of grain size influence until Chin et al. showed an H-P dependence for their own fracture stress measurements also made at 4.2 K.^[140] An evaluation of the aluminum measurements was made as part of a comparison with steel material yield-to-fracture strength measurements.^[141] On an H-P basis, the aluminum ductile fracture stress gave $\sigma_{0F} \sim 540$ MPa and $k_F \sim 54$ MPa·mm^{1/2}. The value of k_F was found to be two times larger than a theoretical brittle fracture stress value employing the theoretical true surface energy measurement, thus giving very significant evidence of plastic flow on cracking even at 4.2 K. Lassance et al. have reported on the micro-mechanics of ambient and higher temperature fracture of 6xxx aluminum alloys.^[142] More recently, a comprehensive report has been made by Khadyko et al. on the importance of texturing in the 6xxx alloys, particularly concerning the influence of alloying elements in solid solution and as precipitates, on the corresponding yield stress and strain hardening behaviors.^[143] Valuable references to historical measurements dating to the early 20th-century researches of Taylor and Elam are included. Shakoori Oskooie et al. have reported on achievement of reasonably high strength and ductility in Al-Mg-Si Al 6063 alloy with a bimodal ultrafine grain and coarse grain structure.^[144] Very interestingly, tensile fracturing was attributed to elongated-hole delamination from internal necking of the coarse grain component, somewhat similar to a description of the true fracture strain attributed to hole joining from de-cohered particles in a ductile fracturing model developed by Petch and Armstrong.^[136] Naseri et al. have obtained similarly improved strength and ductility results for ARB nano/ultrafine-grained AA2024 alloy material;^[145] see relation to Fig. 14 and Reference.^[138]

An H-P-based explanation has been given for the minor amount of shear banding that occurred under the circumstance even in the Basinski case of such low-temperature testing.^[146] In a broader situation, the onset

of shear banding has been attributed to the occurrence of dislocation pile-up avalanches in materials exhibiting high values of the microstructural stress intensity, k_s .^[147] Figure 15 shows on the basis of the inset pile-up avalanche equation, a prediction of susceptibility to shear banding measured by the slopes of lines to coordinate points of theoretical shear fracturing, k_s , versus thermal conductivity, K^* , for a number of metals.^[148] The difficulty of producing shear banding in aluminum may be compared with the well-known susceptibility of shear banding in Ti6Al4V material. Shear strain localization measurements have been recently reported for AA 2219-T8 aluminum alloy in split-Hopkinson compression bar tests at high strain rates in which cracking occurred along the shear bands and was associated with dispersed second phase particles.^[149]

Fatigue

As mentioned above, Gough had produced pioneering comments on the fatigue behavior of aluminum multi-crystals in the 1928 Faraday Society Proceedings.^[3] Aluminum occupies a unique position in the development of aerospace technology. Forsyth et al. Aircraft Establishment colleagues produced a breakthrough description of slip-band extrusions developed on the surface of pure aluminum material under cyclic loading.^[150,151] Cottrell and Hull reported observations of both extrusions and intrusions produced by cyclic slip in copper tested at temperatures as low as 4.2 K.^[152] The observations built on the original description by Thompson et al. of cyclically induced persistent slip bands (PSBs) in copper.^[153] Figure 16 shows connection of surface structure, dislocation (pile-up) activity, and dipole formation as developed under cyclic stress conditions.^[154] Broom, with Whittaker, also first described

an important role for generation of vacancies and enhanced diffusion mechanisms for effecting over-ageing behavior in aluminum alloy systems^[155] and then added comment on cross-slip being an important mechanism in effecting fatigue.^[156]

Armstrong and Phillips reported on specimen size and H–P-based grain size effects in compiled fatigue measurements made on α -iron, low-carbon steel, and α -brass materials,^[157] to be followed by compilation of other H–P description of comparative brass results.^[21] Turnbull and de Los Rios produced H–P measurements made of an endurance limit in commercially pure aluminum material and attributed the dependence to the grain boundaries providing barriers to dominant crack growth.^[158] Agreement between cyclic stress–strain measurements and H–P grain size effect was reported for other aluminum material by El-Madhoun et al.^[159] The nature of PSBs in a number of commercial aluminum materials was modeled via finite element description by Baxter and Wang.^[160] Emphasis was given to PSB behavior being more important than crack growth consideration. Zhang and (Z.G.) Wang produced an important review of grain boundary effects on the cyclic stress–strain curve and fatigue damage with assertion that interaction of PSBs and grain boundaries played a decisive role in intergranular fatigue cracking.^[161] In line then with expectation for ultrafine-grained material, an overview has been given on specific improvements in fatigue behavior produced by equal-channel angular pressing ECAP of copper, aluminum, AA6061 alloy, and α -brass materials.^[162] The results are in agreement with the general description made later of H–P-based grain size reduction providing improved fatigue properties for other ultrafine-grained copper material.^[163,164] Valiev et al. have reported most recently on the very significant advances being made on production via severe plastic deformation

Fig. 15 H–P dislocation pile-up avalanche model for shear banding

Fig. 16 Schematic surface extrusion/intrusion and internal dislocation structure

of bulk ultrafine-grained aluminum alloy and other materials with outstanding improvements in strength and ductility.^[165]

SUMMARY

The plastic deformation and ductile fracturing properties of aluminum and certain aluminum alloys have been reviewed with particular attention given to the use of a Hall-Petch description of grain size aspects of the material behaviors. Initial focus is on the historical role of aluminum in having provided important support for the Taylor theory of dislocation-effected metal plasticity. Microstructural aspects of polycrystalline grain, subgrain, and grain boundary features have been described, especially in the direction of pointing to important strengthening effects at nanoscale grain sizes. An interpretation of the H-P dependence of strength property measurements is provided on the basis of a dislocation pile-up representation of slip bands forcing cross-slip at aluminum and other pure fcc metal grain boundaries. Measurements of temperature and strain rate influences are described in terms of additional relationship to the physically based Zerilli-Armstrong relations that have been developed from a dislocation mechanics description of thermally activated plasticity, including shock-induced deformation and description of comparable deformation rates achieved in *shock-less* isentropic deformations. Measurements are presented for a number of aluminum alloys. Grain size aspects of strain ageing, tensile plastic instability, shear banding, ductile fracturing, and fatigue properties have also been reviewed.

Hardening, Annealing, and Aging

Laurens Ketgerman and D. Eskin

Netherlands Institute for Metals Research, Delft, The Netherlands

Abstract

Aluminum alloys can be divided into two groups: casting alloys and wrought alloys. This article focuses on aluminum wrought alloys. This article will address the hardening, annealing and aging processes of wrought aluminum alloys. Specific topics to be addressed include: hardening mechanisms, annealing, heat treatment, quenching, aging of various commercial aluminum alloys, aluminum-lithium (Al-Li) alloys, precipitation phenomena.

Keywords: Aging; Annealing; Hardening; Precipitation; Wrought alloys.

Aluminum alloys are largely divided into two groups: casting alloys and wrought alloys. For casting alloys, the final product is formed directly without any plastic deformation. By application of special foundry techniques, complex geometries can be formed in near-net shape. Aluminum casting alloys are not considered in this chapter although some general principles of aging and precipitation hardening are also applicable.

For aluminum wrought alloys the products are formed by hot and cold deformation of (semi) continuously cast half-products. Typical deformation processes involved are hot and cold rolling, drawing, forging and extrusion.

The strength of aluminum wrought products can be improved in two different ways:

- cold deformation
- alloying

During cold deformation, crystal defects are generated leading to improved strength properties.

Alloying elements are usually added to aluminum to increase strength. By alloying the strength of aluminum alloys increases by three separate mechanisms:

- Solid-solution hardening. Alloying elements dissolve completely in the aluminum matrix to form a solid solution. The local distortion of the aluminum lattice obstructs dislocation motion leading to increased strength.
- Dispersion hardening. The alloying elements form very fine insoluble dispersion of intermetallic phases. Transition elements typically are added to achieve this effect.
- Precipitation hardening (age-hardening). Alloying elements are brought in solid solution at high temperatures and quenched to room temperature. At

intermediate temperatures below 200°C very fine particles are precipitated from the supersaturated solid solution (SSSS) resulting in substantial increases in strength. The applied thermal treatment is also called aging. Aluminium-Copper is the classic example for precipitation hardening.

Wrought aluminum alloys that obtain their strength through a combination of precipitation and deformation are called heat-treatable. The other alloys obtain their strength through cold deformation and are classified as nonheat-treatable or also as work hardening alloys. The different tempers for these alloys are indicated with a specific code following the AA alloy designation (Table 1). In general heat-treatable alloys receive a T-temper while work hardening alloys are given H-tempers. The general effect of these tempers on alloys strength is given in Fig. 1.

HARDENING MECHANISMS

In general, the strength of aluminum alloys can be increased by several methods:

- Solid-solution hardening.
- Grain-size strengthening.
- Work or strain hardening.
- Precipitation hardening (aging).

Solid-Solution Hardening

Solid-solution hardening involves an increase in tensile strength and yield stress produced by alloying elements in solid solution. The elements in solution produce elastic distortions in the parent lattice thereby acting as a barrier

Table 1 Temper designations for aluminum alloys

Temper	Description
F	As-fabricated
O	Annealed or recrystallized
H	Work hardened; The H is followed by 2 digits
W	Solution heat treated
T	Thermally treated; The T is always followed by 1 or more digits

Fig. 1 Effect of composition and temper on strength of commercial aluminum alloys

to dislocation movements. Although most elements can alloy with aluminum, comparatively few elements have sufficient solid solubility to give a substantial solution hardening effect.

Strengthening from solute atoms arises either from differences in atomic size between the solute and solvent atoms or from differences in elastic modulus.^[1] The size effects can be considered in terms of the different atomic volumes of aluminum (Ω_A) and solute atoms (Ω_S) expressed as:

$$\frac{\Omega_S - \Omega_A}{\Omega_A} \quad (1)$$

Figure 2 clearly indicates that the size effect is the dominant source of solute-strengthening in aluminum alloys.^[2] The combination of solubility and size effect makes Cu and Mg the prominent solutes for solid-solution hardening. On a weight basis Mg is more effective than Cu (although on an atomic basis Cu is more potent). Figure 3 illustrates the effect of Mg in solid solution on the strength of binary Al-Mg alloys.^[3] Both yield strength and ultimate tensile strength increase with increasing Mg level while elongation drops sharply with even small Mg additions. The more rapid rise of UTS compared to YS is explained by the additional effect of Mg on work hardening. Solute atoms also introduce other effects such as

Fig. 2 Strengthening due to atomic size effects^[2]

Fig. 3 Effect of Mg in solution on tensile properties of annealed Al-Mg binary alloys^[3]

dynamic strain aging resulting in serrated yielding in Al-Mg alloys.

The effect of Mg in solid solution on commercial nonheat-treatable alloys is given in Fig. 4.

Grain-Size Strengthening

The effect of grain size on alloy strength is commonly expressed by the well-known Hall–Petch equation:^[4]

$$\sigma_y = \sigma_o + k d^{-\frac{1}{2}} \quad (2)$$

where σ_y is the yield stress of the alloy, σ_o the frictional stress, d the average grain size and k a constant that characterizes the difficulty of transmitting slip across the grain boundary for a given alloy system. Because the value of k is approximately five times smaller than ferrous alloys the grain-size effect in aluminum alloys is not very strong. However considerable strengthening can be achieved at very fine grain sizes, because it has been demonstrated that the Hall–Petch relationship remains operative.^[5]

Fig. 4 Effect of Mg on tensile properties of nonheat-treatable commercial aluminum alloys ^[8]

Work-Hardening

Properties of metals are changed by cold working. For most metals tensile strength, yield strength and hardness increase at the expense of ductility and formability. Work hardening is used extensively to strengthen nonheat-treatable alloys. In addition work hardening increases the strength achieved through solid-solution and dispersion hardening. The typical strain hardening tempers of nonheat-treatable alloys are given in Table 2.

The effect of work hardening is clearly shown in Table 3, where we can see a sharp increase in mechanical properties with increasing amount of cold work, while the elongation decreases significantly.

Precipitation Hardening

The heat treatment including quenching and aging is the most widely used way to improve strength properties of aluminum alloys. The quenching should be understood as the fixation of the high-temperature state of the alloy at lower temperatures. In other words, this procedure produces the supersaturated (in alloying elements) aluminum solid solution. It is noteworthy that the supersaturation can be achieved during casting, upon cooling an ingot or semifinished item in air, or as a result of rapid cooling after special annealing. The aging is a term covering the processes of precipitation hardening which can occur at room temperature (natural aging) or at higher temperatures requiring special heating (artificial aging). In late stages of aging, softening may occur. This is due to the

Table 2 Temper designations for strain-hardened alloys

F	As-fabricated. No control over the amount of strain hardening; no mechanical property limits.
O	Annealed, recrystallized. Temper with the lowest strength and greatest ductility.
H1	Strain hardened.
H2	Strain hardened and partially annealed.
H3	Strain hardened and stabilized.
H112	Strain hardened during fabrication. No special control over amount of strain hardening, but requires mechanical testing and meets minimum mechanical properties.
H321	Strain hardened during fabrication. Amount of strain hardening controlled during hot and cold working.
H116	Special strain hardened, corrosion resistant temper for aluminum magnesium alloys.

Table 3 Tensile properties of aluminum sheet

Alloy-temper	UTS (MPa)	YS (MPa)	Elongation (%)
1100-O	75	25	30

5052-H38	270	220	4

change of structure and distribution of former hardening phases.

The effect of precipitation hardening (or aging) is determined by several parameters listed below.

- The chemical composition of a supersaturated solid solution. This composition is controlled by the initial temperature at which the solid solution is formed and by the cooling rate enabling the fixation of the high-temperature composition at lower temperatures. It should be mentioned that the composition of the supersaturated solid solution and the composition of the alloy are, generally, different. It becomes obvious if you look at a phase diagram of any multicomponent system. Take, for example, casting alloys of the Al-Si system. These alloys usually contain 5–18% Si. However, the concentration of silicon in a supersaturated solid solution is determined by the solubility of silicon at the eutectic temperature and will not exceed 1.65% Si. The content of main alloying elements in the supersaturated solid solution can be dramatically decreased in the presence of other additives and impurities. These additives can bind important elements (e.g. Cu, Mg, and Si) in insoluble phases and, thereby exclude them from the process of aging. Some small additions, however, may favorably affect the internal structure.

- The phase composition of aging products formed upon decomposition of the supersaturated solid solution. Mainly, these products are meta-stable phases in a form of coherent and semicoherent precipitates. The phase composition of these precipitates is, generally, different from that predicted by the equilibrium phase diagram. The precipitation usually starts with the segregation of the solute atoms in some crystallographic planes of the matrix. Then, these preprecipitates (or zones) acquire their own crystal lattice, first similar to that of the matrix. Their structure and composition gradually changes, approaching the structure and composition of the equilibrium phase. The vivid example of these changes is the precipitation of Mg_2Si in Al-Mg-Si alloys, which is discussed further in 2.4. Only for simple alloying systems, where only one phase can precipitate, this phase is a meta-stable modification of the relevant equilibrium phase, e.g. in Al-Si and Al-Cu systems.
- The kinetics of precipitation. This parameter is very important, especially in multi-phase systems. The sequence of phase precipitation depends on temperature and phase properties. Obviously, the temperature provides the thermodynamic stimulus for the decomposition of a supersaturated solid solution. Depending of the annealing temperature a specific meta-stable phase may precipitate. At low temperatures, it is usually zones or coherent precipitates. At higher temperatures, it may be semicoherent metastable phase or the equilibrium phase. In the case of competitive precipitation of several phases, the advantage goes to the phases with a simple structure, formed by faster diffusing elements. This sequence controls the continuous depletion of the solid solution with respect to the elements incorporated in precipitated phases. Accordingly, the kinetics of precipitation can determine the phase composition.
- Temperature and time. These technological parameters affect all previously mentioned phenomena and are extremely important. The combination of time-temperature conditions is called the aging mode.
- The properties of precipitated phases. These properties greatly determine the hardening effect and include the type of bonding with the matrix, the shape, the composition, and the time-temperature stability. Generally, semicoherent precipitates are more efficient for hardening than coherent particles. However, it is true only under similar conditions: the same size and precipitation density. The finer the precipitates and the larger the precipitation density, the higher the strength of the aged alloy. On the other hand, the fracture toughness and other service characteristics are usually better for the solid-solution state (after quenching) or in the stage of zone precipitation. It should be also noted that the structure with meta-stable phases is thermally unstable. Therefore, the creep resistance of aluminum alloys is higher in the overaged state, when more stable phases are formed.

The basic temper designations for heat-treatable alloys are given in Table 4. Solution heat treatment is performed by heating cast or wrought products to a temperature usually 5°C below the solidus. In the case of cast products, two-step homogenization is applied, the first step being some degrees below nonequilibrium solidus. The duration of solutionizing is chosen to be sufficient to dissolve all nonequilibrium phase constituents, allowing the maximum of alloying elements to enter the solid solution. Rapid cooling is frequently used to preserve the high-temperature composition of the solid solution at lower temperatures (quenching).

Age hardening of aluminum-copper-magnesium alloys (Duralumin) was discovered by Alfred Wilm in 1906. The basic requirement for an alloy to be susceptible to age hardening is a decrease in solid solubility of one or more alloying elements with decreasing temperature. The major alloying elements that meet these requirements are copper, lithium, magnesium and zinc. The thermal treatment for age hardening normally involves a solution treatment at high temperature followed by a rapid quench to room temperature to form a supersaturated solid solution (SSSS) and a controlled decomposition at intermediate temperatures. The complete decomposition of the SSSS is a complex process, which may involve several stages including metastable phases. In the initial stages coherent Guinier–Preston zones are formed, named after the two researchers who independently detected these phases from streaks in x-ray diffraction patterns.^[6,7]

Table 4 Temper designations for heat-treatable aluminum alloys

O	Annealed.
F	As fabricated.
W	Solution heat treatment: spontaneous natural aging after solution treatment.
T1	Cooled after high-temperature processing and naturally aged to substantially stable condition.
T2	Cooled after high-temperature processing, cold worked and naturally aged to substantially stable condition.
T3	Solution heat-treated, cold worked and naturally aged to substantially stable condition.
T4	Solution heat treated and naturally aged to a substantially stable condition.
T5	Cooled after high-temperature processing and artificially aged.
T6	Solution heat-treated and artificially aged, usually to the maximum strength.
T7	Solution heat-treated and stabilized or overaged.
T8	Solution heat-treated, cold worked and artificially aged.
T9	Solution heat-treated, artificially aged and cold worked.
T10	Cooled after high-temperature processing, cold worked and artificially aged.

The thermal treatment for aging of aluminum alloys is a three-stage process:

- Solution treatment: dissolution of constituents and intermetallics.
- Quenching: to maintain the supersaturated solution of alloying elements and excess vacancies.
- Aging: precipitation of intermediate phases at room temperature (natural aging) or at elevated temperature (artificial aging).

Solution Heat Treatment

To realize precipitation hardening it is necessary to create a solid solution in which a maximum of alloying elements is in solution. The minimum solution temperature is determined by alloy composition (e.g. the solvus position and eutectic temperature). Exceeding the eutectic temperature can lead to incipient melting of eutectic phases which is detrimental for mechanical properties. A too-low solution temperature can have a significant effect on final properties (Table 5).

Quenching

Quenching is the critical step during a precipitation treatment. During quenching the supersaturated solid solution as well as the excess vacancies need to be maintained. Solute precipitating on grain boundaries and vacancies migrating to interfaces and grain boundaries do not contribute to the aging process. In general the higher the quench rate the better combinations of strength and toughness are achieved. Also stress corrosion and corrosion resistance are better for high quench rates. Only Cu free 7XXX alloys form an exception to this general trend. The disadvantages of a high quench rate are residual stresses

and distortion of the quenched product. Consequently the maximum quench rate depends largely on the dimensions of the product. The quench rate can be controlled by proper selection of the quenching medium and temperature.

Precipitation from Solid Solution

The general condition for precipitation of supersaturated solid solutions requires a fine dispersion of precipitates during aging. The aging temperature needs to be below the equilibrium solvus line as well as below the GP solvus line (Fig. 5). The presence of excess vacancies promotes diffusion and the formation of zones is substantially faster than under equilibrium conditions. During precipitation first clusters of solute atoms are formed followed by the formation of metastable precipitates. The strengthening mechanism is caused by the coherent precipitates of solute atoms.

The difference in size between the aluminum and solute atoms causes elastic stresses in the aluminum matrix. These stress fields inhibit and hinder dislocation movement resulting in higher strength values. Size, form and distribution of GP zones is strongly alloy dependent. Spherical GP zones are formed if the difference in size between aluminum and solute is small (e.g. Al-Zn alloys). For large differences as in the Al-Cu system the zones are plate-like. Typical size for GP zones is 1–5 nm. GP zones are more like local variations in concentration than a separate phase. They are fully coherent with the matrix. The subsequent metastable phases formed during precipitation are semicoherent. A metastable precipitate has its own crystal structure and only along specific crystallographic directions is coherency maintained. The final structure in a precipitation sequence consists of coarse equilibrium precipitates with a marginal effect on strength properties. The different stages during precipitation are illustrated in Fig. 6.

The increase in strength during natural aging is continuous or becomes stable. During artificial aging strength and hardness go to a maximum value and decrease after that. The decrease in strength after extended aging times or at high aging temperatures is called *over aging*. The change

Fig. 7 Isothermal aging curves for AA2014^[9]

in strength during precipitation is given in Fig. 7 as a function of time and aging temperature.

The major effects can be summarised as follows:

- The kinetics of hardening can be retarded or suppressed by decreasing aging temperature.
- Maximum strength decreases with increasing aging temperature.

AGING OF COMMERCIAL ALUMINUM ALLOYS

In this part of the Chapter, we will consider main features of precipitation hardening for major groups of commercial alloys. The sequence of consideration will be as follows: the chemical composition, phase composition, phase properties, kinetics of precipitation, aging modes, and achieved mechanical properties.^[8–10] Some additional numbers may be added to the designation of the basic tempers as already described in Table 4. These additional tempers are given in Table 6.^[10]

Structure of Supersaturated Solid Solutions and Nucleation of Precipitates

The quenching results in the supersaturation of an aluminum solid solution in alloying elements. However, the supersaturation with respect to vacancies occurs simultaneously. This process is known as “quenching of vacancies.” The supersaturation in vacancies may dramatically affect the defect structure of the supersaturated solid solution and the early stages of its decomposition.

Excess vacancies form prismatic dislocation loops in diluted aluminum alloys, whereas, in heavily alloyed solid solutions, helicoid dislocations. The latter are the result of interaction between quenched vacancies and screw dislocations. These structure features can be easily observed in a transmission electron microscope. Alloying with elements forming atom-vacancy complexes increase the number of helicoids and hamper the formation of prismatic loops. The presence of dislocations in the structure of the supersaturated solid solution, generally, facilitates the precipitation of semicoherent phases, because dislocations provide free surface for a semicoherent boundary and, thus decrease the energy of its formation (Table 7). For example, the semicoherent S' (Al₂CuMg) phase in Al-Cu-Mg alloys tend to precipitate on dislocation loops.

The decomposition starts with the formation of submicroscopic regions enriched in alloying elements, these regions having the same structure as the matrix. This stage is called the zone stage, as the Guinier–Preston zones are formed. During this early period of precipitation, the electrical resistivity of the quenched alloy increases in two steps. In the first stage, the resistivity changes very rapidly during first minutes (so-called rapid reaction). After that the resistivity grows very slowly (slow reaction). The first stage is interpreted in terms of segregation of solute atoms on specific crystal planes. These zones are very small and uniformly distributed in the volume. It is believed that this process occurs very rapidly, perhaps by a spinodal mechanism, by fluctuations without nuclei formation.^[11,12]

Let us consider in more detail the difference between “nucleation and growth” and “spinodal” mechanisms of decomposition.^[13] In the case of nucleation and growth, the decomposition is initiated by the formation of energetically stable solute-rich clusters (hetero phase nuclei). Only thermal composition fluctuations with sufficiently large compositional amplitudes can lower the free energy of the system and hence can lead to the formation of stable nuclei. The formation of these nuclei by this mechanism requires a nucleation barrier to be overcome and is characterized by an incubation period. Upon spinodal decomposition, the nonequilibrium solid solution is unstable with respect to the formation of spatially extended thermal composition fluctuations with small amplitudes. Hence, the decomposition is initiated by the spontaneous formation and subsequent growth of coherent composition fluctuations. This type of decomposition occurs without incubation period

Table 6 Additional tempers for heat-treatable aluminum alloys

Temper	Description
Tx51	Stress relieved by stretching. Applies to plate, extruded shapes and drawn tubes stretched up to 3% after solution heat treatment or cooling from an elevated temperature fabricating process; these products receive no further straightening. Tx510 Products with no further straightening. Tx511 Products with minor straightening after stretching to comply with standard tolerances.
Tx52	Stress relieved by compression. Products are stress relieved up to 5% by compression after solution heat treatment or cooling from an elevated temperature fabricating process.
Tx53	Stress relieved by combined stretching and compressing. Applies to die forgings that are stress relieved in the finish die.
<i>Designations for products heat treated from O or F tempers to demonstrate response to heat treatment:</i>	
T42	Solution heat treated from O or F temper and naturally aged to a substantially stable condition.
T62	Solution heat treated from O or F temper and artificially aged.

Table 7 The correlation between the type of precipitates and the place of their formation

Interface type	Grain boundary (G)	Dislocation (D)	Vacancy (V)	Homogeneous nucleation (H)
Coherent (C)	$G_c \rightarrow$	$D_c \rightarrow$ $\downarrow$	$V_c \rightarrow$ $\downarrow$	$\leftarrow H_c$ $\uparrow$
Semicoherent (SC)	$G_{sc} \rightarrow$ $\downarrow$	D_{sc}	$\leftarrow V_{sc}$	$\leftarrow H_{sc}$
Incoherent (IC)	G_{ic}	$\uparrow$ D_{ic}	$\uparrow$ $\leftarrow V_{ic}$	$\uparrow$ $\leftarrow H_{ic}$

and is typical of, for example, Al-Zn and Al-Zn-Mg alloys. In the case of spinodal decomposition, the concentration profile of solute in the matrix looks like a wave with gradually increasing amplitude.

It was established by numerous studies that the actual room-temperature diffusion of solute atoms upon the segregation proceeds at rates several orders of magnitude higher than the normal diffusion at the same temperature.^[14] The most adopted explanation is that the diffusion rate is determined by the vacancy concentration equilibrium at the quenching temperature. This also explains the fact that the cooling rate affects essentially the kinetics of precipitation. However, the question remains: why is the vacancy concentration retained anomalously high during a considerable time, despite numerous sinks?

The possible explanation is that zones are able to absorb and evolve vacancies, acting like a pump.^[15] Part of vacancies is inevitably lost in sinks, and the diffusion rate gradually decreases remaining, however, higher than normal.

Hence, in the early stages of decomposition (so-called zone stage), pre-precipitates or clusters are formed within the matrix crystal lattice. These processes are very

important upon natural aging. The zones are precipitates with the completely isomorphic to the matrix structure. Evidently, elastic stresses and strains arise around these preprecipitates due to local expansion or shrinkage of the matrix crystal lattice. These stress fields interact with dislocations, slow down their movement and, thereby, harden the alloy. There are also other mechanisms of hardening described earlier in this Chapter.

Main strengthening is associated with coherent and semicoherent precipitates that create large elastic distortions at interfaces with the matrix. Nevertheless, what is the interface? Nowadays, the interface is considered as the interface surface proper and the transition regions determining stresses both in the matrix and in the precipitate. The formation of coherent or semicoherent phase is caused by the considerably lower surface energy for such precipitates as compared with the more stable phases. For example, the surface energy of the coherent θ'' (Al₂Cu) phase is three times lower than that for the semicoherent θ' phase.^[16] Upon growth of particles, the coherency is being lost, first along some directions and then at the entire boundary.

Another very important problem is: where do precipitates tend to nucleate? Unlike zones that usually precipitate homogeneously or onto vacancy clusters, the metastable phases may form in various places. This process is usually controlled by crystal defects. Table 7 shows the dependence between the type of precipitates and the place of its formation.^[17] The arrows show the direction of decreasing energy for precipitation.

One can see that coherent phase are predominantly nucleate homogeneously, if their formation does not create large strains. In the case when the specific volume of the zone or the new phase is larger than that of the matrix, the coherent phase will nucleate at vacancy clusters. Semicoherent precipitates tend to form at dislocations, which ease the formation of the semicoherent boundaries. In addition, incoherent particles nucleate at grain boundaries.

Aging in Commercial Al-Cu Alloys

The Al-Cu system is the classics of aging theory and is well studied. At the same time, this system is a base for the entire family of commercial alloys: wrought (Duralumin, 2XXX series) and casting (2XX.0 series). Alongside copper, these alloys may contain magnesium, silicon and transition metals. The magnesium- and silicon-containing materials will be considered below. However, there are a few commercial alloys where copper is the main alloying component, which determines the phase composition and aging phenomena. Some of the alloys are listed in Table 8. It should be noted that simple Al-Cu alloys are not widely used nowadays and are more and more replaced with Al-Cu-Mg wrought alloys or Al-Si-Cu-Mg casting alloys.

The composition of the supersaturated solid solution can be more or less reliably predicted from the equilibrium phase diagram of the Al-Cu or systems that are more

complex. Castings or deformed products from alloys of this group are usually water quenched from high temperatures. These temperatures are chosen to be about 5°C below the equilibrium solidus.

The decomposition of a supersaturated Al-Cu solid solution results in the formation of the following phases: θ'' , θ' , and θ (Al_2Cu). These phases are, respectively, coherent, semicoherent and incoherent (stable). Before the precipitation of the θ'' phase, the Guinier–Preston zones (GPZ) are formed in the aluminum solid solution. It is well adopted that the composition of all these phases is close to the stoichiometry of the Al_2Cu phase. The information on the crystal structure and orientation relationships for phases typical of the Al-Cu system are given in Table 9.^[18]

Upon natural aging, the precipitation starts from the formation of GPZ. The density of their precipitation is $10^{17}\text{--}10^{18}\text{ cm}^{-3}$ at a size of up to 5 nm and a spacing of 2.5–4 nm.^[19] The coherent phase succeeds the zones, being formed either homogeneously in the matrix or onto the zones. The θ'' precipitates appear as disks or thin plates in {100} matrix planes. The typical size of coherent particles ranges from 10 to 100 nm with a spacing from 20 to 100 nm.^[17] These two types of precipitates assure hardening upon natural aging.

The phase composition of alloys aged at higher temperatures (artificial aging) depends on time-temperature conditions. Each metastable phase has its own meta-stable solvus and forms only under it. If the temperature of annealing is higher than the metastable solvus of, say, the θ'' phase, then this phase will never be formed and the decomposition will start immediately with the formation of the semicoherent θ' phase. On the other hand, under suitable temperature conditions the coherent phase can precipitate first and then will be substituted by the θ' phase. The considerably high temperature of artificial aging (170–200°C) provides sufficient thermodynamical stimulus for the successive formation of the entire series of phases, from GPZ to the equilibrium Al_2Cu phase. The particles of the θ' phase usually precipitate onto dislocations (decorating them) and then replace θ'' particles in the matrix as they are losing coherency. The size of semicoherent particles is 10–60 nm at a precipitation density $10^{11}\text{--}10^{12}\text{ cm}^{-3}$.^[17]

It is worth noting that semicoherent particles demonstrate higher strengthening ability than coherent precipitates. This is because several hardening mechanisms can simultaneously act. Therefore, Al-Cu alloys artificially

aged to the stage of θ' precipitation may be much harder than those reinforced only by coherent particles of the close size and precipitation density.

Incoherent particles of Al_2Cu phase have virtually no effect on the strength because of their large size, low precipitation density, and absence of stress fields around.

Small additions of some elements can affect the internal structure of aged Al-Cu alloys. It is known that Cd, In, Sn, Mg, Li, Be, Mg + Ge, and Mg + Si slow down the formation of GP zones and facilitate the substitution of the θ'' phase for the θ' phase.^[18,20,21] The latter precipitates as very fine plate and efficiently hardens the alloy. Cadmium is known to accelerate copper diffusion in solid aluminum.^[22] Beryllium deteriorates hardening upon natural aging.^[23] Transition metals such as Zr, Ti and Mn form dispersoids that provide nucleation sites for relatively large θ' particles and thus decrease the aging effect.^[24]

Table 10 and Table 11 show typical temper modes and mechanical properties of some Al-Cu alloys.

Aging in Commercial Al-Cu-Mg Alloys

The development of Duralumin results in the design of alloys containing, alongside copper, magnesium. This enlarges the possibilities of hardening, now with two phases, Al_2Cu and Al_2CuMg (S). Either phase or both may precipitate with respect to the composition of the super-saturated solid solution. The formation and features of the Al_2Cu -based phases were discussed earlier. However, it is noteworthy to mention that magnesium being in the solid solution (up to 0.4%) efficiently refines θ' particles and increases their precipitation density, thus improving hardening.^[21,25] It is supposed that magnesium increases the

binding energy between solute atoms and vacancies, facilitates the formation of immobile stable complexes, and thus slows down diffusion. These complexes then serve as nuclei for the θ' phase. Alongside improved strength, the creep resistance is also increased due to a higher thermal stability of θ' particles.

The chemical compositions of some commercial alloys are given in Table 12. The composition of the solid solution after quenching from about 500–505°C is close to that of the alloy.

The decomposition of Al-Cu-Mg alloys ($\text{Cu} : \text{Mg} > 2$ at.%) starts with the segregation of copper and magnesium atoms in $\{100\}_{\text{Al}}$ and $\{210\}_{\text{Al}}$ planes.^[18] These clusters are called Guinier–Preston–Bagaryatsky zones (GPBZ).

The sequence of precipitation of quasi-binary $\text{Al}-\text{Al}_2\text{CuMg}$ alloys is as follows: GPBZ, coherent S'' phase, semicoherent S' phase, and stable S phase. The crystal structures of these phases are shown in Table 13.^[18,25–28]

The structure of all S -phase modifications are very close, therefore some authors consider them as a one structure differently distorted due to coherent or semicoherent junction with the matrix.^[26,29] The orientation relationships for GPBZ and S'' precipitates slightly deviate (by 4–5°) from the ideal OR given in Table 9. The transition from one modification to another occurs continuously upon aging, the crystal lattice being rotated and sheared. In the case when S'' and S' particles grow freely, they form typical conglomerates of thin elongated laths, frequently decorating dislocation loops. These particles are aligned with the $\langle 100 \rangle$ matrix lattice direction and have the $(210)_{\text{Al}}$ and $(110)_{\text{Al}}$ habitus. After nucleation, S precipitates rapidly grow filling the entire solid solution volume with agglomerates.

When the alloying level is low (1.5% Cu and 0.7% Mg), the S' phase forms rods in the $\langle 100 \rangle_{\text{Al}}$ direction and $\{100\}_{\text{Al}}$ planes.^[28]

In alloys with the S phase as the main hardener, the strengthening occurs in two distinct stages separated by a plateau, which may last for many hours.^[30] The first stage of hardening, contributing about 70% to the total strength, is attributed to the (Cu, Mg) cluster formation. These clusters are precursors of GPBZ and S'' phase, which

precipitation occurs in the second stage of hardening. The *S'* and *S* phases are formed onto dislocation loops during the stage of a plateau.

In the alloys with an excess of copper (with respect to the stoichiometry of the *S* phase), the Al_2Cu phase is formed additionally. Mondolfo^[18] concludes that the latter phase plays the major role in hardening alloys with the ratio Cu : Mg = 8. On decreasing the ratio to 4, both phases participate in strengthening. Moreover, the *S* phase dominates in the range of Cu : Mg ratio from 4 to 1.5. On further decreasing the ratio, the Al_6CuMg_4 phase has to precipitate. However, there are only few data on such alloys.

It should be noted that GPB zones are more thermally stable than GP zones. According to Silcock^[25] in an alloy with Cu : Mg = 7, the maximum hardness is achieved by the combination of phases: θ' and *S''* (at 130°C and 165°C) and *S''*, *S'* and θ' (at 190°C). The coherent *S''* phase can be retained at considerably high temperatures. We can conclude that the Al_2Cu phase acts more efficiently at low aging temperatures (below 165°C), whereas the role of the Al_2CuMg phase becomes dominant at higher temperatures.

The TTT diagram for aging of a 2024-type alloy is given in Fig. 8.^[31] This diagram shows the phase composition and hardening effect in time-temperature axes.

The presence of silicon impurity in commercial Al-Cu-Mg alloys may change essentially the phase composition and precipitation sequence of aging products, thereby affecting the mechanical properties. These phenomena will be considered below in the section about Al-Cu-Mg-Si alloys. The addition of silver in Al-Cu-Mg alloys can considerably improve properties after aging and increase thermal stability of structure and properties due to the change of phase composition. The decomposition of alloys, containing more magnesium than copper and small additions of silver, occurs with the formation of a so-called *X'* phase in addition to the *S* phase.^[30] The *X'* phase has a hexagonal structure and is very close in composition to the *S* phase, except small content of Ag (5 at.%).

In the alloys with high Cu:Mg ratio, a new phase conventionally designated as Ω is formed instead of the θ' phase. This phase has a tetragonal structure with lattice

Fig. 8 Time-temperature diagram for aging of a 2024-type alloy

parameters $a = 0.6066$ nm and $c = 0.496$ nm or an orthorhombic structure with $a = 0.496$ nm, $b = 0.859$ nm and $c = 0.848$ nm. The precipitates of the Ω phase appear as fine plates, the (Ag, Mg) clusters and GP zones earlier formed on $\{111\}_{Al}$ planes continuously transforming to the Ω phase. As distinct from GP zones, which are depleted of copper and enriched in magnesium and silver, the Ω phase has the copper concentration close to that in the Al_2Cu phase, magnesium and silver being evolved to the interface with the matrix.^[32] Even small impurities of silicon (0.15%) completely suppress the formation of the Ω phase.

In addition to the Ω phase, the so-called σ phase may be formed in Al-Cu-Mg-Ag alloys (3–4% Cu, 0.45% Mg, 0.4% Ag), especially in composite materials.^[33] This phase has a composition of $Al_5Cu_6Mg_2$ and a cubic structure with $a = 0.831$ nm. It should be noted that, according to the phase diagram, the $Al_5Cu_6Mg_2$ phase cannot be in equilibrium with aluminum. The only possibility of its appearance is the strongly metastable state of an alloy and the effect of silver (as a stabilizer of this phase). The σ phase has a simple cube-on-cube orientation relationship with the aluminum matrix. It precipitates as the semicoherent phase with

a high solvus (above 700°C), which makes it quite stable at high temperatures, above 200°C. On decreasing the Cu:Mg ratio from 10 to 7, the precipitation of the σ phase begins to dominate over the formation of the Ω phase. Although these phases may coexist with each other and with metastable modifications of θ and S phases. In any case, silver addition improves the thermal stability of Al-Cu-Mg alloys and, nowadays, there are several Ag-containing alloys intended for use in airspace industry.

Typical temper modes and mechanical properties of Al-Cu-Mg alloys are listed in Table 14 and Table 15.

Aging in Commercial Al-Mg-Si Alloys

Very different in structure, properties and destination alloys belong to this system. There are casting alloys containing 4–18% Si and 0.15–1% Mg and there are very widely used extrudable alloys of the 6XXX series, containing 0.5–1.5% Si and 0.5–1.5% Mg with various ratios. The compositions of some commercial alloys are given in Table 16.

It is very important to note that the aging effect and properties are very much dependent on the ratio between magnesium and silicon in the supersaturated solid solution. The excess of silicon (with respect to the stoichiometry of the Mg_2Si phase) can considerably change the kinetics of precipitation and the phase composition.

The decomposition of the supersaturated solid solution results in precipitation of the β (Mg_2Si) phase and free Si (in the alloys with its excess). The coherent β'' phase is an

efficient hardener and participates in processes of natural and artificial aging. In the stage of softening, it gives place to the semicoherent β' phase, which is considerably stable. The decomposition starts directly with the formation of β' particles at temperatures above 300°C, and the sole equilibrium β phase precipitates upon annealing above 400°C.^[34]

The transformation between Mg_2Si modifications is a subject of discussion. Really, there is no reliable explanation how the monoclinic phase can transform to hexagonal or orthorhombic and then to the cubic equilibrium phase. Moreover, the development of high-resolution electron microscopy gave rise to new discoveries. It was found that, unlike all other known metastable phases in aluminum alloys, the semicoherent phase might have several modifications. The cause of this unique phenomenon is still unclear. Maybe it is due to the uniqueness of the Mg_2Si phase proper. This phase is composed of metal and semiconductor, which have to determine its unusual behavior.

The composition of metastable phases, i.e. Mg:Si ratio, is different from that of Mg_2Si (Mg:Si = 2 at.%). The Mg:Si ratio continuously increases in the series GPZ, β'' , β' , β . In other words, metastable phases are enriched in silicon. The structures and orientation relationships of phases typical of Al-Mg-Si alloys are listed in Table 17.^[18,35–40]

The maximum strength is achieved in alloys with an excess of silicon and in the stage of β'' precipitation. There is no unanimous opinion on the reasons of that. It is more or less adopted that the silicon-vacancy complexes acts as nucleation sites for the coherent phase.

The nonequilibrium solid solution of magnesium and silicon in aluminum decomposes even at room temperature. In the balanced alloys or in the alloys with Mg:Si ratio above 1.73 wt% the decomposition proceeds in the following steps: the formation of needle-like zones along the $\langle 100 \rangle_{Al}$ crystal direction; the ordering of their structure and the formation of β'' needles; the transition from β'' needles to β' rods; and the formation of the equilibrium β phase as plates or cubes.^[41] During artificial aging of dilute Al-Mg-Si alloys ($Mg_2Si < 0.8\%$) the coherent β'' phase nucleates onto zones. In this case, the internal structure formed upon preliminary natural aging provides

the conditions for the formation of very fine, uniformly distributed β'' precipitates.

The transition between metastable modifications is likely to occur separately. In other words, coherent precipitates dissolve, semicoherent particles are formed at dislocations, and the coherent phase may precipitate on dislocations or grain boundaries. However, there is an opinion that these transformations occur by the diffusionless, shear mechanism (like martensite).^[14] It should be noted that during high temperature annealing (at 300–350°C) the β' and equilibrium β phases may coexist for a long time, large precipitates with the structure of β' being almost incoherent.^[34]

Zones are precipitated very intensively, the precipitation density being $3 \times 10^{15} \text{ mm}^{-3}$ and the size, $6 \times 20\text{--}100 \text{ nm}$. The coherent phase has the same precipitation density with the size somewhat larger, $5 \times 16\text{--}200 \text{ nm}$.^[42] The zone stage lasts from 5 h to 8 min at 150–200°C, respectively, while the transition to the β' phase requires 200 to 8 h in the same temperature range.^[43]

Solute copper accelerates the precipitation of the β'' phase, refines its particles by three times and promotes the homogeneous distribution of precipitates.^[44] This effect can be observed at copper concentrations lower than 2%.

Alloys with an excess of silicon has one major difference from alloys with Mg:Si ratio lower than 1.73 wt%. In these alloys, free silicon precipitates and affects the entire situation. Let us consider briefly the precipitation of silicon from the supersaturated solid solution.

The Al-Si system has all necessary features enabling one to expect precipitation hardening. However, no hardening occurs during precipitation of silicon from the supersaturated solid solution. Silicon atoms segregate on

vacancy clusters or free silicon nucleates on dislocation loops very rapidly after quenching. Due to the large difference in lattice parameters between silicon and aluminum, the precipitates almost immediately lose coherency. In the temperature range from 150°C to 250°C, the complete precipitation of silicon takes 17 h to 30 min, respectively.^[45,46] Silicon particles appear in the structure as prisms, rods or plates. Their size and interparticle spacing is considerably larger than those required for hardening effects. Solute copper may affect the precipitation of silicon, refining its particles.^[17] Hence, silicon does not directly participate in strengthening.

However, its effect on the sequence of precipitation and the variation in the composition of the supersaturated solid solution is very important. Silicon accelerates the formation and increases the precipitation density of spherical (Al, Mg, Si) zones. These zones act like nuclei for the coherent β'' phase. Recently, it has been found that the Mg:Si ratio in the semicoherent phase β' phase is lower in the alloys with an excess of silicon, as compared with balanced alloys (1.21 and 1.75 at.%, respectively).

From the analysis of numerous literature data, we can conclude that the sequence of precipitation in Al-Mg₂Si-Si alloys is as follows (in parentheses the temperature range according to DSC analysis:^[45]

- Formation of magnesium and silicon segregates in the matrix crystal lattice (below 100°C).
- Nucleation of needle-like zones onto these segregates (200–250°C).
- Nucleation of free silicon with rapidly lost coherency. The (Al, Mg, Si) zones remain unchanged (240–320°C).

- Formation of the coherent β'' phase onto (Al, Mg, Si) zones (below 450°C).
- Formation of the semicoherent β' phase (below 450°C).
- Formation of the equilibrium β phase (above 400°C).

The delay between quenching and artificial aging in Al-Mg₂Si-Si alloys decreases the hardening effect. However, small copper additions can minimize this effect. Cadmium, indium, and lead also diminish this effect, but only upon aging at temperatures below 160–170°C.

Some Al-Mg-Si alloys contain Sb, Pb or Sn that are added either to modify the Al-Si eutectics or to improve machinability of alloys. These elements can considerably worsen the mechanical properties, binding part of magnesium in insoluble, brittle particles of the Mg₂X type. In this case, the efficient concentration of magnesium in the supersaturated solid solution is decreased.

Temper modes and mechanical properties of some Al-Mg-Si alloys are given in Table 18 and Table 19.

Aging in Commercial Al-Cu-Mg-Si Alloys

The Al-Cu-Mg-Si system provides a base for several groups of commercial wrought and casting alloys: Duralumin (2024 with silicon impurity), forging alloys (2014), and high-strength and heat-resistant Al-Si alloys. The compositions of some alloys are given in Table 20.

On one hand, the phase composition of these alloys is extensively studied for many years. On the other hand, usually the decomposition phenomena in such alloys are considered separately for either alloy or alloy groups, which results in contradictory results when comparing different

compositional ranges. The main problem is that the phase composition of these alloys is very complex and can hardly be predicted using the equilibrium phase diagram. Several phases can precipitate solely or in combination depending on the proportion and concentration of alloying elements.

The decomposition of multicomponent supersaturated solid solutions is a very important problem of modern physical metallurgy. It is likely that the final structure formed in an alloy after decomposition is determined by the composition of a supersaturated solid solution and the sequence of phase precipitation or, in other words, by kinetics. It is clear that this structure, in turn, determines the mechanical properties.

The phase composition of wrought alloys is more or less known. Depending on the Cu:Mg and Mg:Si ratios the phase composition in the stage of maximum hardening varies from S' to $S' + \theta'$ then to $\theta' + \beta''$ and, finally, to $\theta' + \beta'' + \text{Si}$. There is controversial information on the phase composition of alloys, containing 2–4% Cu and magnesium and silicon in the Mg:Si ratio less than unity (excess of silicon). According to the equilibrium phase diagram, there should be the cubic quaternary Q (Al₄CuMg₅Si₄) phase instead of Mg₂Si. The Q phase has a complex cubic structure with $a = 1.263$ nm^[18] or a hexagonal structure with $a = 1.04$ nm and $c = 0.405$ nm.^[47] Some authors report that they have observed “precursors” of the Q phase in the stage of hardening.^[48,49] The main argument is that these precipitates giving the electron diffraction pattern very close to that of the β'' (or β') phase contain copper. For example, Yao et al.^[50] have found in Al-Mg-Si-Cu alloys air-cooled from solutionizing temperature the so-called B' phase with lattice parameters similar to those of the β' phase ($a = b = 1.05$ nm and $c = 0.405$ nm), but containing copper. Note that the suggested structure of the B' phase is similar to that of the Q phase.^[47] However, the same phase is observed in copper-free alloys. This may attest for the possible dissolution of copper in a Mg₂Si-based phase. Recently, Cayron and Buff^[51] reported

that the structure of the B' (or β'_{c}) phase could be easily transformed to the structure of the Q phase by substituting silicon atoms for copper. Of course, there should be the Q phase in these alloys, at least in the equilibrium state. However, the question remains opened when it will form, during hardening in the temperature range from 150°C to 250°C, or later after dissolution of hardening β'' precipitates, or only at higher temperatures.

The mutual effects of alloying elements are very strong. Copper and excess silicon refine β'' precipitates; magnesium facilitates the formation of the θ' phase instead of θ'' but with very close distribution and size parameters.^[42,52,53]

The most complicated is the analysis of casting Al-Si alloys in which the composition of the supersaturated solid solution and the composition of the alloy are completely different and determined by the limit solubilities and the solution treatment mode. The maximum solubilities of copper, magnesium and silicon in Si-rich alloys are 4.0%, 0.3% and 0.77%, respectively.^[18] It has been shown that silicon-containing phases precipitate only upon artificial aging, whereas the hardening at room temperature is determined by GP and GPB zones.^[54]

The examination of the entire compositional range of supersaturated solid solutions in Al-Cu-Mg-Si alloys may help to understand the problem. This was done for alloys containing 4% Cu and aged at 170°C for 20 hr.^[36]

The results of these investigations are given in Fig. 9. We can see that the composition of the supersaturated solid solution affects dramatically the phase composition of aging products. Depending on the Mg:Si ratio, Duralumin (2024 type) fall into the phase regions (Al) + S' , (Al) + S' + " or (Al) + " + β'' ; forgeable alloys of the 2014 type fall into the phase region (Al) + " + β'' ; and heat-treatable silumins have the phase composition (Al) + " + β'' + Si. The change of the

phase composition is accompanied by the essential change in the internal structure. The structure composed by " and β'' precipitates is much finer than that containing S' phase.

When discussing these results, we have to mention the following:

- The metastable phase composition in the range of 2XXX series alloys corresponds with their equilibrium phase composition according to the phase diagram.
- The phase composition of alloys with an excess of silicon differs from that according to the equilibrium phase diagram.
- According to the equilibrium phase diagram, all casting Al-Si alloys with magnesium and copper have to contain the quaternary Q phase.

The difference between the equilibrium and metastable phase composition can be explained in terms of precipitation kinetics. The decomposition occurs in the following sequence: clusters and zones (Mg, Si) and (Al, Cu); Si; β'' ; and ". In such a scheme of precipitation, the supersaturated solid solution gradually depletes of Si, Mg and Cu due to the formation of binary phases, and there is no material left to form the Q phase. The precipitation of other phases with simple composition is thermodynamically more favorable. So, the β'' phase precipitates instead of the Q phase. Later, the coherent phase can transfer to the semicoherent variant of β' or B' , and finally to the equilibrium Q phase.

The change of phase composition affects the aging response and mechanical properties of alloys. It has been shown that the maximum hardening effect and the highest strength refers to the phase composition with hardening phases β'' and ". This is an unusual result. Previously, the S' phase was considered as the most efficient hardener in the alloys of this system. The results given in Table 21 demonstrate that the introduction of Si in the stoichiometric ratio with Mg in high-purity Duralumin increases the

yield strength and fatigue endurance with other vital properties preserved.^[36] This is due to the dramatically changed the phase composition and internal structure. The same is true for casting alloys.

It should be noted that usually silicon is considered as a harmful impurity in wrought and casting aluminum alloys. This element really decreases ductility and fracture toughness of solid-solution type alloys. This is mainly due to the formation of intermetallics with iron impurity. However, being introduced in nearly stoichiometric ratio with magnesium (Mg:Si = 1.73 wt%) in alloys pure with respect to iron, silicon changes the phase composition of aging products and improves characteristics of the alloy.

Impurities and small additions can considerably affect the hardening effect of Al-Cu-Mg-Si alloys, mainly due to the binding of main alloying elements in insoluble particles and to the decreasing content of copper and magnesium in the supersaturated solid solution. It has been found that iron, nickel and cobalt reduce the copper concentration in the supersaturated solid solution from 4 to 2.5–3.5%. Antimony and lithium lower the magnesium content. These effects are illustrated in Table 22.^[55] Note that mutual alloying with iron and manganese restores the composition of the solid solution and the tensile properties.

Typical temper modes and mechanical properties of some commercial Al-Cu-Mg-Si alloys are shown in Table 23 and Table 24.

Aging in Commercial Al-Zn-Mg-(Cu) Alloys

The compositions within the Al-Zn-Mg-(Cu) system form important series of commercial materials. The quaternary alloys yield the highest strength for commercial aluminum wrought (7XXX series) and casting (7XX.0 series) alloys. The chemical compositions of some alloys are given in Table 25.

The solid solution range in these alloys are very wide and almost all zinc, magnesium and copper can be introduced into the supersaturated solid solution during quenching. It is worth to note that the supersaturated solid solution in copper-free Al-Zn-Mg alloys can be obtained even during rather slow cooling, in air.

First, we consider the Al-Zn-Mg system. This alloying system is well studied, although there are still disputes about the origination of GP zones and the meta-stable

phase composition. The following phases are formed during aging: GP zones (MgZn); η' ; η (MgZn₂); T' ; and T (Al₂Mg₃Zn₃ or (AlZn)₄₉Mg₃₂). As Mg:Zn ratio ranges from 2:5 to 1:7, the precipitation sequence goes through zones and coherent precipitates to the η phase. At Mg:Zn = 0.5–6, the decomposition finishes with the formation of the T phase.^[18] Two types of GB zones are distinguished in Al-Zn-Mg alloys: GP1 are formed during natural aging and GP2 (or vacancy-rich clusters) originate during quenching and are likely to be precursors for the η' phase. The metastable η' phase forms in the compositional range much wider than the (Al) + η region on the equilibrium phase diagram, covering part of the (Al) + T phase field. The very important feature of this system is that the η phase may have a series of orientation relationships, typical of the aging mode and the alloy composition. This specific feature is reflected in the designation of η precipitates with a subindex. The η_i phases precipitate in the temperature range from 100°C to 200°C and can nucleate either on η' particles or independently. The data on the crystal structure and orientation relationships of possible phases in Al-Zn-Mg alloys are shown in Table 26.^[18,56]

The addition of up to 1% copper to Al-Zn-Mg alloys does not affect significantly the precipitation mechanism. Copper remains mainly in the solid solution, not forming own phases. Higher copper content contributes to hardening either by increasing the stability of GPZ (copper atoms enter the zones) or by altering the composition of η phase during aging above 150°C, or by the formation of the S' (Al₂CuMg) phase.^[57] Aksenov et al.^[57] also showed that the addition of 1–2% Cu to Al-Zn-Mg alloys increases the metastable solvus of the hardening η'_2 phase and therefore contributes to additional hardening by improving the stability of this phase. According to Mondolfo,^[18] the main constituents of alloys containing 5–8% Zn, 23% Mg and up to 1.5% Cu are the MgZn₂-AlCuMg and Al₂Mg₃Zn₃-Al₆CuMg₄ phases, which form series of solid solutions between isomorphous phases from Al-Mg-Zn and Al-Cu-Mg systems.

The properties of Al-Zn-Mg-Cu alloys are much dependent on the total concentration of alloying elements. If the overall content of Zn, Mg and Cu exceeds 9%, the alloys exhibit the highest strength at expense of corrosion resistance, weldability and toughness. In the range of alloying concentration from 6% to 8%, the balanced complex of properties can be achieved. In addition, at the concentration range from 5% to 6%, the fabricability becomes paramount and stress-corrosion susceptibility vanishes.

The natural aging of Al-Zn-Mg-(Cu) alloys occurs very efficiently and continues for years. Due to this instability in properties, these alloys are seldom used in the RT-aged condition (W temper). Stable properties, higher strengths and fracture toughness, and improved corrosion resistance are obtained after various modes of artificial aging. In difference from Al-Cu-Mg-(Si) and Al-Mg-Si alloys aged typically in the range from 160°C to 190°C, the Al-Zn-Mg-(Cu) alloys receive higher properties upon annealing in the temperature range from 115°C to 130°C.

The maximum strengthening is associated with precipitation of coherent GP zones and the semicoherent η' phase. The solvus temperature of GP zone formation increases with magnesium and zinc concentrations. The zones are very small (2–3.5 nm) and spherical in shape, whereas the η' phase forms round- or plate-shaped particles. The GP zones nucleate homogeneously in the matrix and gradually transform to either η or T phases with respect to the Mg:Zn ratio. The η phase precipitates in various shapes such as plates, rods and laths, depending on the orientation relationship.^[56] Crystal defects such as dislocations, small- and large-angle boundaries represent sites for the preferential formation of semi-coherent or incoherent particles. On aging at temperatures above the solvus of GPZ or during slow cooling upon quenching, the precipitation of these not hardening phases occurs and decreases the final strength of the

alloy. Hence, the right choice of the quenching rate and the aging temperature is very important for receiving necessary properties.

A time-temperature diagram showing the phase composition of aging products in a 7075-type alloy is given in Fig. 10.^[31]

The most widely used aging mode for Al-Zn-Mg-(Cu) alloys is a two-step aging. The aim of the first step (100–110°C) is to grow up GP zones that are stable at higher temperatures and provide sites for the formation of meta-stable hardening phases. During the second step (150–160°C) the alloy acquires desirable properties. There are several purposes of the two-stage aging: (i) to diminish the harmful effect of intermediate natural aging (or delay between quenching and artificial aging); (ii) to reduce the overall treatment time; and (iii) to improve corrosion resistance.

High-strength Al-Zn-Mg-Cu alloys are very sensitive to stress corrosion, which limits their application. The susceptibility to stress corrosion is due to inhomogeneous precipitation of semicoherent and incoherent phases and due to the formation of so-called precipitation-free zones near grain boundaries. The nucleation of GP zones is much dependable on the efficient vacancy concentration in the supersaturated solid solution. As the grain boundaries provide good vacancy sinks, the nearby regions can be depleted of vacancies or solute atoms, or remain supersaturated without decomposition.^[18] Special heat treatment modes were designed to improve the stress-corrosion resistance of these alloys. These tempers are based on

**Fig. 10** Time-temperature diagram for aging of a 7075-type alloy

the fact that overaging may decrease the selective corrosion at grain boundaries. The practice is to use either two-step aging (100–120°C, 1–24 hr and 160–175°C) or one-step aging at 160–175°C but with well-controlled heating rate. In both cases the aim is to produce numerous GPZ stable at higher temperatures, and then transform them to homogeneously distributed intermediate and stable phases upon over-aging.

Additions of transition metals also are aimed on the improving corrosion resistance due to the redistribution of precipitates, grain refinement and hardening the precipitation-free zones.

The temper modes and mechanical properties of some commercial Al-Zn-Mg-(Cu) alloys are listed in Table 27 and Table 28.

Aging in Commercial Al-Li Alloys

Alloys containing lithium attract more and more attention during recent two decades. These alloys have several advantages: low weight, high rigidity, excellent fatigue and cryogenic toughness. Most of these materials are wrought and heat treatable. Main application is aerospace industry. Each 1% Li within the limit solubility decreases the density of an alloy by 3% and increases the Young modulus by 5%. There are several groups of alloys with lithium: Al-Cu-Li; Al-Mg-Li; and Al-Cu-Mg-Li. Binary Al-Li alloys have not found any commercial application, however the precipitation phenomena in these alloys is worth considering in order to better understand the aging of more complex materials. Some alloy compositions are given in Table 29.

The decomposition of the Al-Li supersaturated solid solution occurs with the homogeneous formation of the ordered δ' (Al_3Li) phase which later gives place to the equilibrium AlLi phase.^[58] At usual concentrations of

Li (1.5–2.5%), the solvus of the intermediate phase is about 150–250°C. The very fine, spherical precipitates or clusters of Al_3Li are formed during quenching, and the artificial aging results only in their growth. The rapid lithium diffusion along dislocation lines, grain boundaries and interfaces with dispersoids causes the formation of precipitation-free zones and discontinuous precipitation of δ . On further aging the coherent δ' phase transforms to the semicoherent and, finally, incoherent δ' (AlLi) phase. The latter appears as plates and frequently forms onto grain boundaries. It is likely that the AlLi phase nucleates and grows independently of its precursor.

The crystal structure and orientation relationships of phases formed in various Al-Li alloys are given in Table 30.^[18,58,59]

Al-Li alloys are unique with respect to microstructures formed during aging. The δ' phase once precipitated retains its coherency even after long aging times. Additionally, long aging of Al-Cu-Li alloys at temperatures above 190°C produces grain-boundary precipitates of the icosahedral phase, which is quite unusual for common processing procedures. The behavior of the δ' phase is very similar to that of the Al_3Sc phase.^[60]

However, the precipitation-free zones and grain-boundary precipitates alongside homogeneously distributed coherent particles inside grain determine the limitation of Al-Li alloys—fast crack propagation and uneven dislocation slip with relevant stress accumulation and cracking.

In commercial alloys, the dislocation slip is homogenized and the precipitation-free zones are reduced by introducing dispersoids (e.g. Al_3Zr) and semicoherent/incoherent precipitates such as T_x , θ (Al_2Cu) and S' (Al_2CuMg).

Magnesium and copper are the most widely used additions to Al-Li alloys. They improve strength by solid solution and precipitation hardening and minimize the formation of precipitation-free zones, thereby increasing

fatigue endurance and fracture toughness. Zirconium stabilizes substructure, preventing the development of recrystallization. In addition, the introduction of transition metals, such as Zr and Sc, considerably slows down the lithium diffusion and the coarsening of δ' particles.^[61] Moreover, the presence in the structure of coherent or semicoherent Al_3Zr and Al_3Sc particles provides places for preferential nucleation of the δ' phase. The latter forms so-called composite particles with the core of Al_3TM and the envelope of Al_3Li .

The precipitation sequence in Al-Li-Mg alloys is: supersaturated solid solution, δ (Al_3Li); Al_2LiMg . The only effect of magnesium at early stages of decomposition is the reduced solid solubility of lithium. Therefore, the precipitation density of δ' increases. Later, magnesium and lithium form the ternary compound. The latter is incoherent and nucleates on grain boundaries or dislocation networks during quenching or overaging.

In the Al-Li-Cu alloys, the decomposition occurs as follows; supersaturated solid solution, GPZ, Al_2Cu (θ'' , θ' , θ) or Al_3Li (δ') and, finally, T_1 (Al_2CuLi). Instead of T_1 , other T_x phases (see 60) can be formed depending on the Cu:Li ratio. On decreasing this ratio, the equilibrium phase composition changes from θ to T_B , T_1 , T_2 and, finally, to $AlLi$. On overaging, the R phase forms in addition to T_B and T_2 phases.^[59] Generally, copper accelerates the decomposition and hardening in Al-Li alloys. The hexagonal T_1 phase appears in structure as hexagonal-shaped plates. With

respect to the supersaturation, T_1 nucleates either on GPZ or at dislocations.

During precipitation in an Al-2.7% Li-1.9% Cu alloy, plates of the T_1 phase rapidly fill the entire volume of the grain dividing it into cells filled, in turn, with δ' particles.^[62] As a result of this structure formation, the yield strength of the alloy increases and the deformation becomes more uniform. However, the latter effect may be much less pronounced if there are regions free of T_1 particles.

Huang and Ardell^[63] demonstrated that the equilibrium phase diagram cannot predict the phase composition after aging. They studied two alloy, containing, respectively, 2.3% Li; 2.85% Cu and 2.90% Li; 0.99% Cu. Both alloys contained also 0.12% Zr. According to the equilibrium phase diagram, the first alloy has to contain T_1 and T_2 phases whereas the second one, δ and T_2 . However, the TEM study revealed that both alloys contained after aging δ' and T_1 , and the first alloy in addition, θ' . The latter phase frequently serves as a substrate for δ' . The θ' phase is observed up to the peak hardness range, afterwards it dissolves giving place to the T_1 phase.

Figure 11 demonstrates a time-temperature diagram for phase distribution and hardening of a 1450 (Al-Li-Cu-Zr) Russian alloy. Alloying with both magnesium and copper makes the phase composition and precipitation sequence more complex.^[59] In addition to δ' and T_x phases, the S' (Al_2CuMg) and R (Al_5CuLi_3) phases precipitate, contributing to further improved hardening. The S'

particles decorate subboundaries and prevent or delay the development of dynamic recovery, thus improving high-temperature stability of the alloy up to 250°C.

Typical temper modes and mechanical properties of some Al-Li-based alloys are given in Table 31 and Table 32.

PRECIPITATION PHENOMENA IN ALUMINUM ALLOYS WITH TRANSITION METALS

The main peculiar feature of transition metals (TM) in aluminum alloys is the formation of supersaturated solid solutions during solidification. The higher the cooling rate, the larger the solubility of TM in solid aluminum. The supersaturated solutions obtained in this way are characterized with much higher stability than ordinary supersaturated solid solutions formed by copper, magnesium, zinc, silicon, and lithium upon quenching. The temperature of decomposition for Al-TM solid solutions is between 250°C and 650°C, depending on the transition metal.

Modern ingot and casting metallurgy operates with cooling rates of 10–100 K/sec. At such cooling rates, the aluminum solid solution can be saturated with TM up to the equilibrium limit solid solubility in eutectic systems or to the equilibrium concentration of TM in the liquid phase in peritectic systems.

The use of rapid solidification techniques, such as atomization, splat cooling and melt spinning, can increase the cooling rate up to 10⁷ K/sec and enrich the solid solution to much larger extent. Table 33 and Table 34 demonstrate the supersaturation degree, phase composition and hardening effect of some Al-TM binary alloys.^[60] The high structural and phase stability of Al-TM alloys makes these alloys promising for commercial use. This stability is connected mainly with very low diffusion rates of these elements in solid aluminum and sometimes with good structural match between crystal lattices of TM aluminides and aluminum (a cubic structure with $a = 0.404$ nm).

In binary systems, transition metals react with liquid aluminum either by eutectic (Mn, Fe, Sc, Ni) or peritectic (Cr, V, Zr, Ti, Mo) reactions. The type of the phase diagram determines some differences in the alloy behavior. The formation of a supersaturated solid solution in peritectic systems requires deeper undercooling, which is evidenced by the existence of a threshold cooling rate, about 10² K/sec. On the contrary, the supersaturation in eutectic systems increases continuously with undercooling (or cooling rate). The decomposition in alloys of eutectic systems occurs at lower temperatures and proceeds more rapidly than in peritectic-type alloys. The diffusion coefficients of elements forming eutectic systems with aluminum are by an order of magnitude higher than those of peritectic systems.

It should be also noted that the dendritic segregation formed upon solidification in Al-TM alloys cannot be easily eliminated by homogenization. This is obviously due to low diffusion rates of transition metals, which range from 10^{–14} to 10^{–12} cm³/sec at 500°C.

There are several mechanisms, by which transition metals act in aluminum alloys. These are grain refinement of the as-cast structure, slowing down or preventing the recrystallization of deformed alloys (structural hardening), and precipitation hardening. The first two mechanisms are widely used in commercial aluminum alloys, which frequently contain small additions of Ti, Mn, Zr, and Cr. The third mechanism is less used. There are several causes of

Table 34 Parameters of binary Al-TM alloys and effect of precipitation hardening

System	Phase	Crystal structure	Limit solubility (C), at %	Temperature of decomposition, °C	Effect of precipitation hardening, $\Delta H / C$ [at. %]
Al-Mn	Al_6Mn	Orthorhombic: $a = 0.6498$ nm; $b = 0.7552$ nm; $c = 0.8870$ nm Cubic (meta stable $Al_{12}Mn$): $a = 0.747$ nm	0.88	300–350	10
Al-Cr	Al_7Cr	Orthorhombic: $a = 2.48$ nm; $b = 2.47$ nm; $c = 3.02$ nm,	0.41	450–500	51
Al-Zr	Al_3Zr	Tetragonal: $a = 0.4006$ nm; $c = 1.727$ nm Cubic (meta stable): $a = 0.407$ nm	0.093	400–450	154
Al-V	$Al_{11}V$	Cubic: $a = 1.4586$	0.21	500–550	31
Al-Ti	Al_3Ti	Tetragonal: $a = 0.3848$ nm; $c = 0.8596$	0.17		—
Al-Sc	Al_3Sc	Cubic: $a = 0.4104$ nm	0.28	250–350	208

this. Firstly, there are only a few transition metals that form coherent or semicoherent precipitates during decomposition of the supersaturated solid solution. Actually, there are only zirconium and scandium (see Table 34). Secondly, the temperature ranges of precipitation hardening in commercial wrought alloys (150–200°C) and in Al-TM alloys (250–450°C) are very different. Therefore, one has to choose which mechanism of hardening is preferable, by usual hardening phases considered previously in this Chapter or by aluminides of transition metals.

The challenge is to use the precipitation hardening with Al-TM phases in non-heat-treatable aluminum alloys, e.g. Al-Mg. This way was applied to the development of Al-Mg-Zr-Sc alloys and gave excellent results.^[60] All mechanisms of transition metals in aluminum alloys are due to the formation of considerably fine aluminides either during solidification or during annealing. Mostly, the aluminides formed upon solidification have an ability to refine grains, serving as nucleation sites for aluminum solid solution. Lamikhov and Samsonov^[67] showed that

the refining ability of transition metals added to 99.99% pure Al decreases from Sc to Ni in Period IV and from Zr to Mo in Period V. The incompleteness of the d -shell and the crystal structure of aluminides are likely the most important parameters determining the refining effect.

The hindering of recrystallization processes occurs by pinning-down small-angle boundaries and dislocations by fine, not necessarily coherent, aluminide particles (dispersoids). These particles are usually formed during high-temperature decomposition, e.g. during solution treatment (which is homogenization for main alloying elements and heterogenization for transition metals). Yelagin^[68] analyzed the effects of transition metals on recrystallization of aluminum and its alloys. Binary alloys were cast, annealed at 500°C, hot rolled at 420–450°C, annealed at 450°C, and cold rolled. Table 35 demonstrates the maximum increments of recrystallization temperatures upon addition of TM. The analysis of the data shows that (i) the recrystallization temperature in binary alloys of aluminum with Period IV TM increases after a certain threshold concentration which is close to the limit solubility of TM at a temperature of solution treatment; (ii) in the case of Period V TM, the recrystallization temperature increases even with very small additions; and (iii) some TM cause pronounced maxima of the recrystallization temperature against the concentration, these maxima being correlated with the limit solubility of TM in aluminum.

Transition metal acts as an efficient antirecrystallizer agent under the following conditions: incomplete $3d$ electron shell with minimum electrons; large difference in atomic radii with aluminum; formation of supersaturated solid solution upon solidification; and the decomposition of this solid solution with precipitation of thermally stable fine dispersoids.

Let us briefly consider the effects of some commonly used transition metals in aluminum alloys.

Chromium is a usual addition to Al-Mg, Al-Mg-Si and Al-Mg-Zn alloys. It is used to control grain structure in wrought products by delaying or preventing

recrystallization during heating or hot working. The formed substructure is favorable for stress-corrosion resistance and fracture toughness. However, when a hardening phase tends to precipitate onto Cr-containing dispersoids, the quench sensitivity may increase.

Iron is usually considered as a harmful impurity in aluminum alloys. Nevertheless, its addition along with manganese in 8XXX series alloys produces good combination of strength and ductility at room temperature and helps to retain strength at elevated temperatures. This is due to the fine grain size stabilized by dispersed iron-rich precipitates. In order to prevent the depletion of the solid solution of copper and magnesium in 2XXX series alloys, iron is combined with manganese or nickel. In this case, the amount of insoluble phases containing copper, magnesium, silicon and iron is essentially decreased, being replaced by AlFeMnSi and AlFeNi compounds.

Manganese is a very typical addition in many commercial aluminum alloys. Manganese has the highest solid solubility among TM in aluminum and can provide solid solution hardening as well. However, the most important is the structural hardening due to the decomposition of Al-Mn supersaturated solid solution. Alloys of the Al-Cu-Mg system usually contain 0.5–0.8% Mn, which simultaneously improves strength and ductility of extruded products. Manganese (up to 1.25%) is a main alloying element in 3XXX alloys used for can production. Its purpose is to allow high deformation degrees and to prevent grain growth. These effects are due to the slowing down recrystallization and considerably uniform distribution of manganese precipitates throughout the grain volume. At the same time, manganese precipitates increase the quench sensitivity of heat treatable aluminum alloys. Manganese is also the cheapest addition in aluminum.

Scandium is a new element in aluminum alloys. The interest to this element is increasing during recent decade thanks to the unique combination of properties in Al-Sc alloys.^[60] All valuable features of scandium in aluminum are due to the formation of the Al₃Sc phase either during solidification or upon decomposition of the supersaturated solid solution. The vital feature of this phase is a cubic structure with the lattice parameter only slightly different from that of aluminum (0.4104 nm and 0.404 nm, respectively). This is the best match in all known equilibrium phases. The antirecrystallizing effect of scandium is very high and can be used in almost all commercial aluminum alloys. However, the precipitation hardening, which is very efficient in Al-Sc alloys (Table 36), can be successfully applied only to nonheat-treatable alloys, such as Al-Mg and Al-Mn alloys.

It should be noted that scandium is quite expensive, therefore its concentration should be as low as possible. It was found out that the mutual introduction of Sc and Zr allows one to decrease the amount of scandium to 0.15–0.2% and even improve mechanical properties, service characteristics, and thermal stability. The reason is in the

Table 35 Maximum increments of the temperatures of recrystallization onset (t_r^s) and finish (t_r^f) in Al-TM alloys

Element	Atomic radius, nm	C, at%	Δt_r^s , K	Δt_r^f , K

formation of two coherent cubic phases with close crystal structures (equilibrium Al_3Sc and metastable cubic Al_3Zr). These phases together precipitate in the temperature range 300–400°C, which is between effective temperature ranges of binary Al-Sc and Al-Zr alloys, and produce higher strength than in binary alloys. The advantage of ternary alloys becomes more pronounced at higher annealing temperatures and on longer exposures.^[69] The decomposition occurs by the formation of coherent spherical Al_3Sc and Al_3Zr precipitates, latter being finer than former. On increasing the temperature of annealing, Al_3Zr particles grow slowly retaining coherency and harden the matrix, whereas Al_3Sc precipitates coarsen, loose coherency and pin-down dislocations. In the temperature range from 350°C to 450°C and on soaking times up to 200 hr, the size of Al_3Zr particles ranges from 5 to 11 nm and that of Al_3Sc , from 25 to 35 nm. The alloying of aluminum alloys with Sc and Zr is the mainstream in physical metallurgy of these alloys.

Zirconium proper is a very important addition to structural aluminum alloys. The main role of this element is to slow down or prevent the development of recrystallization and, thereby, improve strength and service characteristics of wrought products. The supersaturated solid solution of Zr in aluminum formed upon solidification decomposes during solution treatment and hot deformation with the formation of fine dispersoids of the metastable cubic Al_3Zr phase. These precipitates very efficiently pin down dislocations and small-angle boundaries, promoting the formation of polygonized or very fine-grained recrystallized structure in deformed products. Such structure not only increases mechanical properties, but also decreases the anisotropy of properties and stress-corrosion susceptibility. Additions of zirconium (as well as Sc) to Al-Li alloys assure a more homogeneous distribution of hardening phases, especially Al_3Li , and reduce the precipitate-free zones near grain boundaries. This effect is because cubic Al_3Zr acts like a substrate for the precipitating Al_3Li phase. As a result rather evenly distributed composite particles are formed, increasing the strength and toughness of an alloy.

Let us consider in more detail two groups of commercial alloys. First group includes Al-Mn alloys and represents up to now the only one series of commercial

wrought aluminum alloys containing solely transition metals. Second group consists of Al-Mg-Sc alloys and vividly shows the possibility of precipitation hardening with the aid of transition metals.

Commercial Al-Mn Alloys

Commercial Al-Mn alloys are among oldest aluminum materials. The first alloy known today as 3003 was introduced in 1906. In the end of 1920s a 3004 alloy appears. Amazingly but these alloys are still in use without major changes in composition. This proves the value of manganese as an important alloying element. Table 37 shows the compositions, treatment modes and properties of commercial Al-Mn alloys.

The strength of the 3003 alloy is essentially higher than that of commercially pure aluminum, and the 3004 alloy is even considerably stronger. The dispersion and structural hardening with manganese aluminides is in a base of the structure and properties of these alloys. Besides, the solid-solution hardening of magnesium is employed in the 3004 alloy.

Manganese easily forms supersaturated solid solution in aluminum upon ingot casting ($V_c < 10^2$ K/sec). This solid solution decomposes at temperatures above 325°C with precipitation of fine Al_6Mn or more complex ($AlFeMn$) and ($AlFeMnSi$) dispersoids. There is no real precipitation hardening. However, these dispersoids efficiently hinder grain growth upon recrystallization and provide for the formation of fine-grained structure in sheets and other deformed products. High iron and silicon content and small amounts of copper and magnesium also tend to refine the grain size.^[18] Iron is also very important in these alloys from the viewpoint of texture. It prevents the formation of earing upon deep drawing due to the control of texture.^[9]

All these alloys possess high corrosion resistance, weldability, excellent machinability and good resistance to grain growth. The tensile properties considerably increase with decreasing temperature and, on the other hand, retain sufficient level up to 200°C. They are used in production of general-purpose structures, chemical-resistant and food-compatible equipment, and packaging. The 3004 alloy is the main material for beverage cans.

Table 37 Chemical compositions, temper modes and mechanical properties of commercial Al-Mn alloys[#]

[#]All Al-Mn alloys contain up to 0.25% Cu, 0.70% Fe, and 0.3–0.6% as impurities.* Annealed (O).** Worked H14.*** Worked H34.

Commercial Al-Mg-Sc Alloys

Conventional commercial Al-Mg alloys (5XXX series) are distinguished for their excellent corrosion resistance, weldability and machinability. They contain up to 6% Mg. Despite high solubility of magnesium in aluminum and the fact that this solubility decreases with temperature, there is no hardening associated with precipitation of the Al_3Mg_2 phase. The particles of this phase are formed mainly on grain boundaries, being incoherent and polycrystalline. The main hardening mechanism in these alloys is solid-solution hardening by magnesium retained in the solid solution. Usually Al-Mg alloys are used in annealed or strain-hardened states. To improve strength and prevent grain growth upon recrystallization, commercial Al-Mg alloys contain small additions of manganese, chromium and titanium. The drawback of these alloys is low strength, especially yield strength. The strongest Al-Mg alloys exhibit the yield strength only as high as 150 MPa in the annealed state and up to 420 MPa after severe working.^[9]

To overcome this limitation, a few commercial Al-Mg alloys containing scandium and zirconium were developed in 1970s–1980s in Russia.^[60]

The alloying of aluminum with magnesium increases its lattice parameter and decreases the dimensional misfit between Al_3Sc and the matrix to 0.54% in an Al-6.5% Mg alloys. As a result, the coherency of Al_3Sc remains stable to higher temperatures (450°C) and on longer exposures (up to 10 hr), assuring a higher thermal stability of Al-Mg-Sc alloys. The recrystallization starts in an Al-6.5%Mg-0.2% Sc alloy at about 400°C and never finishes up to the liquidus temperature. The studies performed,^[60,70,71] confirmed that fine coherent Al_3Sc precipitates formed during aging of Al-Mg-Sc alloys at 300–350°C increase the starting recrystallization temperature by 50–175°C and make the complete recrystallization impossible. Additions of zirconium further improve mechanical properties and thermal stability of structure and allow a lower concentration of scandium. The formed structure makes these alloys naturally superplastic, allowing elongation up to 700% at 450–470°C.^[72]

Several mechanisms of hardening are employed in Al-Mg-Sc alloys: grain refinement during casting, precipitation hardening during annealing, and structural hardening by preventing dynamic and static

recrystallization. In addition, the solid-solution hardening with magnesium acts in these alloys just in the same manner as in Al-Mg alloys. Annealing of ingots before deformation should be performed in the temperature range from 250°C to 350°C. In this case, the decomposition of a supersaturated solid solution of scandium and zirconium occurs with the formation of fine spherical coherent precipitates of Al_3Sc and Al_3Zr 40–300 nm in size. These particles greatly contribute to the strength by precipitation and structural hardening. Commercial Al-Mg alloys containing 2–6% Mg and 0.1–0.6% Sc form a 157X series of Russian Alloys. Hot- and cold-worked semifinished products from these alloys are used in worked and annealed states for the structures of ships and airspace vehicles. All these alloys possess high corrosion resistance, perfect weldability, good properties at room and cryogenic temperatures, sufficient strength, and natural superplasticity.

A 1570 alloy contains 5–6% Mg and small additions of Sc, Zr, and Mn^[73] and is the strongest of the known commercial Al-Mg alloys. The stronger the working, the higher the strength. After annealing at 320°C for 1 hr, rolled sheets, forgings and extruded shapes from this alloy exhibit the following tensile properties: $UTS = 380\text{--}440$ MPa; $YS = 250\text{--}340$ MPa, and $El = 16\text{--}20\%$. By comparison, the strength of a 1570 alloy is 100 MPa higher than that of commercial Sc-free Al-Mg alloys.

The structure formed in hot rolled and annealed plates from a 1570 alloy demonstrates nonrecrystallized grains ($150 \times 50 \times 20 \mu\text{m}$ in size); equiaxed subgrains ($5 \mu\text{m}$ in size), Al_6Mn dispersoids ($0.4 \mu\text{m}$ in size) at grain boundaries, and coherent Al_3Sc and Al_3Zr precipitates (less than 20 nm in size) inside subgrains.^[74] These structural features are responsible for the properties of commercial products from Al-Mg-Sc alloys.

However, the acting mechanisms of hardening determine a disadvantage of these alloys. The maximum strength is achieved during annealing (aging) prior to deformation, which makes the working more difficult and does not permit use of intermediate anneals without the loss of strength.

The commercial Al-Mg-Sc alloys are valuable and indispensable in applications where one needs the combination of light weight, sufficient strength at room and cryogenic temperatures, excellent corrosion resistance and weldability.

Hardness–Yield Strength Relationships in Al-Zn-Mg(-Cu) Alloys

Murat Tiryakioğlu

University of North Florida, 1 UNF Drive, Jacksonville, FL, 32224, United States

Abstract

Mean pressure developed during Vickers and Rockwell hardness testing of Al-Zn-Mg-Cu alloys is reviewed. Relationships between mean pressure and yield strength are introduced for these alloys by using both Vickers and Rockwell hardness data from the literature. Results have shown that the slope of the mean pressure–yield strength relationships is 0.355 for Vickers tests and 0.264 for Rockwell B tests. The y-intercepts calculated for best fits are all negative, implying that the representative strains in both tests have exceeded the yield strain. Results also have indicated that mean pressure is affected by the indenter geometry and therefore is not a universal hardness number.

Keywords: Indentation size; Mean pressure; Meyer hardness; Rockwell hardness testing; Vickers hardness testing.

INTRODUCTION

Because of their high strength-to-density ratio, wrought Al-Zn-Mg-Cu alloys have been used extensively in aerospace applications. Quality assurance practices in the aerospace industry usually require that tensile tests be conducted on specimens excised from the aluminum parts.^[1] Although this practice yields reliable results, excising the tensile coupons not only is time-consuming, but also in some applications leads to the destruction of the part. Therefore, nondestructive methods to estimate the tensile properties, especially yield strength (σ_y), are of interest to materials engineers. One of the most common techniques to estimate yield strength is hardness testing because of its nondestructive nature, leaving behind only an indentation. Moreover, mechanical data can be gathered quickly without the need for excising samples for testing.

Vickers and Rockwell hardness scales are widely used for aluminum alloys. In Vickers hardness, a conical indenter is forced into the specimen at a predetermined load (L). The load (in kg) is then divided by the indentation surface area to find the Vickers hardness number (H_V). In Rockwell hardness testing, either a conical or a spherical indenter is forced into the specimen, first at a minor load, establishing an initial depth of indentation. Major load is subsequently applied, and then released, maintaining the minor load. The difference in depth between when the major load is applied and after it is released is used to calculate the Rockwell hardness number (H_R).^[2] H_R is an arbitrary number and lacks a physical significance whereas Vickers hardness has a physical meaning. A unified way of interpreting the results from the two tests is needed, especially to provide accurate estimates of yield strength. In addition, there are conflicting messages presented in the

literature about the relationship between yield strength and hardness. This study is motivated by this gap in the literature.

BACKGROUND

In all commercial hardness tests, an indenter of a specified geometry and size is forced onto the surface of the specimen at a predetermined load. Either indentation size or depth is used to calculate hardness number. In all hardness tests, the mean pressure under the indenter, P_m , alternatively referred to as the Meyer hardness,^[3] is found by dividing the load by the projected area of indentation, A_i :

$$P_m = \frac{L}{A_i} \quad (1)$$

In calculating Vickers hardness, H_V , load is divided by the contact area of indentation, not the projected area. Therefore, P_m and H_V are related by

$$P_m = 1.079 \cdot g \cdot H_V \quad (2)$$

where g is the gravitational acceleration. In hardness tests using a spherical indenter, mean pressure can be written as

$$P_m = K \left(\frac{d}{D} \right)^{m-2} \quad (3)$$

where K is a material constant that, according to Hoyt,^[4] represents “the resistance of the metal to initial penetration.” The exponent m in Eq. 3 is known as the Meyer exponent and has a value near 2.5 for fully annealed

metals, and for fully work-hardened materials, it is close to 2.^[5] The flow stress under the indenter, σ_f , is related to mean pressure as follows:

$$\sigma_f = \frac{P_m}{C}. \quad (4)$$

Hill et al.^[6] developed a solution for the stress distribution under a wedge indenter and showed that the pressure normal to the surface of the indenter tip can be found as

$$P_m = 2\tau_c(1+\theta), \quad (5)$$

where τ_c is the critical maximum shear stress and θ is an angle in the geometric model developed by Hill et al. that is a function of the half angle of the nose of the wedge. For a flat punch, $\theta = \pi/2$. For Vickers indentation, Tabor^[5] assumed that the model for a flat punch would be a good approximation. Tabor also used the Huber–Mises criterion, such that:

$$2f_c = 1.15 \sigma_Y. \quad (6)$$

Combining Eqs. 5 and 6 and taking $\theta = \pi/2$, we obtain

$$P_m = 1.15 \sigma_Y \left(1 + \frac{\pi}{2}\right). \quad (7)$$

Therefore:

$$P_m = 2.956 \sigma_Y. \quad (8)$$

In tensile tests of fully work-hardened materials, stress increases elastically to yield strength, after which it remains constant despite increasing strain, as depicted in Fig. 1a, which shows that the flow stress, σ_f , which produces a representative strain (ϵ_r) in hardness testing, is approximately equal to σ_Y . In many early studies on the hardness of metals, the materials were specifically chosen to be fully work hardened, ensuring that flow stress was equal to yield strength so that stress calculations always resulted in an estimate of the yield strength. For instance, Tabor^[6] conducted experiments on three fully work-hardened metals, namely tellurium lead, copper, and mild steel, and found C to be 2.90, 2.80, and 2.80, respectively, which are similar to the C value in Eq. 8. Shaw and DeSalvo,^[7] in their analysis for a blunt axisymmetric indenter, found that $C=2.82$, which is essentially the same as the one found by Shield^[8] ($C=2.84$) for a round punch pushing against a deforming metal. Larsson^[9] investigated Vickers hardness test by finite element modeling and found that $C=2.80$. Since Tabor's initial statement that $C \approx 3$, many researchers assumed the mean pressure under an indenter to be three times the tensile yield strength of the metal. This has led to confusion among researchers as well as practitioners in metals that are not fully work hardened.

Fig. 1 Schematic illustration of the stress–strain diagrams of (a) fully work hardened and (b) work-hardening metals. The representative strain in hardness testing is also indicated along with the stress that corresponds to it

Vickers hardness test is designed to produce geometrically similar indentations because the angle of contact between the metal and the edge of the indenter does not change with indentation depth. Consequently, a constant representative strain is produced under the indenter, which was stated as 0.08 by Tabor^[5] and 0.07 by Johnson.^[10] Other researchers^[11–22] suggested different representative strains, ranging from 0.0115 to 0.36. Recently, Tiryakioğlu and Robinson^[22] analyzed tensile curves of 7010-T7 forgings on which Vickers hardness tests were also conducted, following the same methodology outlined by Tabor.^[6] They determined that the representative strain in Vickers hardness is equivalent to a tensile strain of 0.024. Therefore, there is strong evidence in the literature that the strain in Vickers hardness testing is produced by a flow stress well in excess of the yield strength. In metals that are not yet fully work hardened, σ_f is larger than σ_Y . Consequently, the effect of work hardening that occurs during indentation must be accounted for

$$\sigma_f = \sigma_Y + \Delta\sigma, \quad (9)$$

where $\Delta\sigma$ is the increase in stress due to work hardening during deformation up to the characteristic strain. This is

demonstrated schematically in Fig. 1b. Combining Eqs. 4 and 9, we obtain:

$$\sigma_Y = \frac{P_m}{C} - \Delta\sigma. \quad (10)$$

Equation 10 is consistent with the results in the literature^[23–28] because the linear relationship between σ_Y and Vickers hardness consistently yielded a negative intercept in specimens that work harden during tensile deformation. For $C = 2.82$, the slope ($\Delta\sigma_Y/\Delta P_m$) is calculated as 0.355.

P_m – σ_Y RELATIONSHIPS IN 7XXX ALLOYS

Vickers Hardness

Tiryakioğlu et al.^[25] analyzed the Vickers hardness–yield strength relationship in 7010 aluminum alloy plates and forgings. The results of the three independent studies,^[28–30] with a total of 246 data points, were found to overlap. The mean pressure–yield strength relationship for the three studies is shown in Fig 2. Note that the best-fit equation is:

$$\sigma_Y = 0.355 P_m - 181.2. \quad (11)$$

It is significant that the slope is 0.355, corresponding to a C value of 2.82, as predicted by Shaw and DeSalvo^[7] and very close to the values predicted by Shield^[8] and Larsson^[9] and found experimentally by Tabor.^[6] It is also significant that the y-intercept has a negative value, consistent with results in the literature for other metals.

Based on the result that three independent studies yielded the same relationship, the author^[23] analyzed data from the literature to determine whether the same relationship would also apply to other 7XXX alloys. The study involved data from the literature for 6 commercial 7XXX and 4 experimental Al–Zn–Mg–Cu alloys, covering 19 datasets from 16 independent studies. In these datasets, six different product forms that ranged from single crystals to extrusions were used. A total of 172 data points were reanalyzed. The results are presented in Fig. 3. The coefficients of determination for the fits to commercial and experimental alloys were 0.971 (Fig. 3a) and 0.982 (Fig. 2b), respectively. Hence, the hypothesis that the slope of 0.355, found for 7010 aluminum alloy, represented a fundamental relationship was verified by fits to all datasets. This result also confirms that the constraint factor of 2.82 should be used in Vickers hardness tests for Al–Zn–Mg–Cu alloys.

In the same study, the author^[23] also determined that the value of $\Delta\sigma$ for each dataset was different. Further analysis of $\Delta\sigma$ values did not reveal any correlation to alloy temper, processing route, or average yield strength of the datasets. Hence, the value of $\Delta\sigma$ remains empirical. When the loads at which the Vickers hardness data were collected

Fig. 2 The change in yield strength with mean pressure in 7010 alloy plate and forging

Fig. 3 The change in flow stress with mean pressure for (a) 7XXX and (b) experimental Al–Zn–Mg–Cu alloys
Source: Data from the work of Tiryakioğlu.^[23]

in different studies were reviewed, it was concluded that the load did not affect the slope of the Meyers hardness–yield stress relationship for Vickers hardness testing. Hence, Vickers hardness can be used to estimate the change in σ_Y regardless of the load that is used during testing.

Rockwell Hardness

Unlike in Vickers, the representative strain in Rockwell hardness testing is not constant because hardness tests with ball indenters do not produce geometrically similar indentations;^[31] the angle of contact between the metal and the spherical indenter changes with indentation depth.

The representative strain in spherical indentations is found by

$$\varepsilon_r = \lambda \frac{d}{D}, \quad (12)$$

where λ is a constant, approximately equal to 0.2 as suggested by Tabor.^[5] Similar to representative strain, mean pressure is affected by indenter diameter as well as the load, such that:^[2]

$$P_m = K \frac{2}{m} D^{\frac{4-2m}{m}} L^{\frac{m-2}{m}}. \quad (13)$$

Equation 13 suggests that for fully work-hardened metals ($m=2$), $P_m = K$. Hence, K represents the Meyer hardness of the metal when it achieves full plasticity.

The diameter of indentation, d , when the indenter and specimen are in full contact, can be written as

$$d = 2\sqrt{h(D-h)}, \quad (14)$$

where h is the total depth of indentation. Once the load is removed, elastic stresses under the indenter are released, resulting in a significant decrease in depth of indentation. The diameter of indentation, however, remains essentially constant.^[5]

In regular Rockwell testing, the initial (minor) load is 98 N (10 kg force). The magnitude of the total (major) load depends on the scale and is listed as 981 N (100 kg force) for B scale. For regular Rockwell tests, H_R is found by

$$H_R = 130 - 500 h_{maj}, \quad (15)$$

where h_{maj} is the difference in depth of indentation between the major and minor loads (mm). The B scale uses a 1.59 mm (1/16 in.) diameter ball. To convert Rockwell hardness number to Meyer hardness, h needs to be determined, so that Eq. 14 can be used to calculate d . Rockwell hardness testing, however, does not use the full depth of indentation. Although h_{maj} can be easily found by rearranging Eq. 15, the depth due to minor load, h_{min} , remains to be determined. Lysaght and Debellis^[32] provided a procedure to calculate h_{min} based on Rockwell B scale (H_{RB}). The linear relationship can be written as:

$$h_{min} = 0.002 (20 - 0.146 H_{RB}). \quad (16)$$

Combining Eqs. 15 and 16, the total depth of indentation, h , is calculated as:

$$h = 0.002 (150 - 1.146 H_{RB}). \quad (17)$$

Tiryakioğlu and Campbell^[2] found Eq. 17 to be accurate for cast aluminum alloys.

The results of Lee et al.^[33] for 7050 and 7075 alloys were used to determine the $P_m - \sigma_Y$ relationship for Rockwell hardness testing. In each dataset, the sample size was 174. HRB values were converted to h by using Eq. 17 and subsequently to d values by Eq. 14. Mean pressure values were then calculated by using the major load of 981 N and the indentation diameters. The results are presented in Fig. 4, which shows that the slope of the two lines is identical. The slope of 0.264 implies $C=3.79$. Additionally, the slope is significantly lower than 0.355, the one obtained in Vickers hardness data in Figs. 2 and 3. Similar to Figs. 2 and 3, the relationships have a negative y-intercept. It is not clear why the two alloys have different y-intercepts, as previously observed for Vickers hardness test results for Al-Zn-Mg alloys. Therefore, it is recommended that $\Delta\sigma_Y/\Delta P_m = 0.264$ be used but the y-intercept has to be determined experimentally.

The representative strain values were calculated by using Eq. 12 and $\lambda = 0.2$. The representative strain levels in the Rockwell hardness data of Lee et al.^[33] ranged between 0.092 and 0.151. Therefore, strain is well in excess of that corresponding to yield strength. Moreover, the stress under the indenter can be expected to approach the saturation stress at which full plasticity is attained.

The difference in slopes between Figs. 2 and 4 indicates that the Meyer hardness is also affected by the indenter type and therefore is not a universal hardness number. This result is consistent with the findings of Sakai.^[34]

Fig. 4 The change in yield strength with mean pressure produced in Rockwell hardness testing for 7050 and 7075
Source: Data from the work of Lee et al.^[33]

CONCLUSIONS

- The analysis of datasets from the literature has shown that the slope of mean pressure–yield strength relationships in Al–Zn–Mg–Cu alloys is 0.355 and 0.264 for Vickers and Rockwell hardness tests, respectively. These slopes can be used to estimate the change in yield strength. If yield strength should be estimated, y-intercepts should be determined experimentally.
- The slopes correspond to *C* values of 2.82 and 3.79 for Vickers and Rockwell hardness tests, respectively.
- In all datasets, the y-intercept is negative, indicating that the representative strains exceeded the yield strain.
- Calculated representative strains in Rockwell hardness data ranged between 0.092 and 0.151. At these strain levels, the stress under the indenter can be expected to have approached the saturation stress.
- Meyer hardness is also affected by the indenter type and therefore is not a universal hardness number.

Abstract

In many applications within the automotive industry, the formability of sheets or extruded material is of great importance. The formability is strongly influenced by the chemical composition and the thermomechanical treatment prior to deformation. Grain size and morphology as well as texture and the presence of constituent particles make the material heavily anisotropic and the properties direction dependent. In all cases, shear band formation leads to surface topography during bending, and fracture initiates from the grooves. The crack propagation after initiation is, however, dependent on the grain size and the number and distribution of particles.

Keywords: Aluminum alloys; Constituent particles; Formability; Microstructure; Texture; Three-point bending.

INTRODUCTION

Aluminum sheets and extruded profiles are often formed into more complex shapes by cold deformation. This requires a good combination of strength and ductility from the material as well as good control and understanding of the forming process. In the automotive industry, aluminum material of thicker gauge extrusions may be formed by bending of inner structures, whereas outer skin made of thin sheets has to withstand the extreme deformation during the hemming operation in which a 180° bend is obtained.^[1]

The first theoretical approaches to describe bending of metallic materials were purely mechanical descriptions.^[2–5] According to Wang et al.,^[6] the understanding of the mechanics and development of mathematical models describing bending were threefold from an industrial perspective. The first was prediction of spring back and shape accuracy control. The second was failure prediction and better understanding of bendability and third was estimation of needed forces and strength analysis and design of dies. Compared to a uniaxial tensile test, the bending test is much more complex. In 1960, Datsko and Yang^[7] came up with a simple relationship between the reduction in area (RA) after tensile testing and the bendability. None of these purely empirical relationships do, however, take into account the fact that several microstructural features such as work-hardening, constituent particles, and texture influence the bendability. An extruded profile or rolled sheet will not behave in an isotropic way

during bending as it is assumed for many of the old models.^[8] In later years, there has been more focus on trying to describe and model what happens in the material during bending from a phenomenological perspective.^[8–12]

In the following, a brief description of the three-point bending test and its mechanics will first be given. Subsequently different material characteristics that strongly affect the bendability of heat-treatable aluminum alloys will be presented and discussed.

THE THREE-POINT BENDING TEST

The three-point bending test is included in the international standard ISO 7438 Metallic materials—Bend test.^[13] The three standardized bend tests are the three-point bending test (bending device with two supports and a former), the cantilever bend test (bending device with a clamp), and bending into a specified angle of shape (bending device with a V-block and a former). Hemming, which is much described in the literature due to the use in automotive body panel forming^[14–18] may involve all three bend methods. The industry may require that the test should follow more specific guidelines, which are in accordance with the standard, e.g., the guidelines proposed by Daimler Chrysler.^[19]

Figure 1 shows a typical three-point bending test setup, where a universal test machine is equipped with a three-point bending tool. The lower part consists of two supporting rolls, and the upper part is the forming tool. The ISO 7438

states that *unless otherwise specified*, the distance between the supporting rolls should be three times the thickness of the test specimen plus the diameter of the forming tool $\pm$ half a specimen thickness. The force is logged as a function of vertical displacement of the upper tool, and the test is stopped as soon as the force–displacement curve shows a drop indicating instability as shown in Fig. 2. After bending when the forming tool is released, elastic recovery (spring back) will occur. The angle α in Fig. 3 is manually measured

Fig. 1 Universal test machine equipped with tools for three-point plane strain bending

after the test, and the bending angle then corresponds to $180^\circ - \alpha$. This means that the higher bending angle, the better formability.

It is often referred to as the bendability of a material. The bendability is not the bending angle mentioned above, but is defined as the ratio between the minimum bending radius ($r_{\min}$) and the thickness (t) of the test specimen without fracture occurring.^[6,7,20–23] Datsko and Yang^[7] have proposed an empirical relationship between the bendability and the RA obtained by tensile testing:

$$\frac{r_{\min}}{t} = \frac{C}{RA} - 1,$$

where C is an empirical parameter. The lower the $r_{\min}/t$ ratio, the better the bendability.

Mechanics of the Three-point Bending Test

During three-point bending test of a strip, the material on the inside of the bend is subjected to compressive loading, while the material on the outside of the bend is exposed to tensile loading as schematically illustrated in Fig. 4a. During elastic deformation, the bending strain ϵ_x may be considered linearly distributed through the thickness of the specimen with the neutral axis coinciding with the center axis of the sheet and with equally large absolute values of the maximum tensile and compression bending strains,^[6] see Fig. 4b. As the loading continues, plastic deformation is introduced, and the strain distribution through the thickness becomes nonlinear. In the case of sharp bends, the neutral axis moves toward the inside of the bend,^[24] this is illustrated in Fig. 4c. In a strain state as illustrated in Fig. 4c, the tensile straining on the outside of the bend is larger than the compression straining on the inside, which again results in a thickness

Fig. 2 Typical force–displacement curve in a three-point bending test. Failure is defined at the point with maximum force level

Fig. 3 Manual measuring of the bending angle after testing

Fig. 4 (a) Schematic illustration of the major stresses present in three-point bending and their direction relative to the bending axis (BA); compressive forces toward the tool and tensile forces at the outer side. (b) Strain distribution in bending cross section along the BA for small strains, and (c) nonlinear strain distribution for large strains. CA is the central axis of the sheet, NA is the neutral axis of the sheet, and t is the sheet thickness

reduction of the sheet at the bend section.^[24] However, in contrast to a uniaxial tensile test, a necking instability is not present in the three-point bending test.^[11] If the width of the strip is sufficiently large, the strains in the width direction are small and can be neglected, i.e., the bend section is subjected to a state of plane strain.^[24] The material near the surfaces of the bend experiences stress states close to plane-strain tension or plane-strain compression, although a strain gradient in the thickness direction is present.

Onset of Fracture and Crack Propagation during Bending

Failure in metal forming is usually defined as onset of necking or onset of fracture. The onset of necking can be defined as the point when global elastic unloading outside of the neck starts.^[11] Since the bending specimen is constrained from necking, stable bending deformation is interrupted by fracture caused by shear band formation. Onset of shear banding leads to nucleation, growth, and coalescence of microvoids,^[25,26] which eventually creates a macroscopic crack surface. Onset of shear banding is likely to initiate at the surfaces of the specimen.^[11] As fracture occurs on the surface of the tensile side, the crack propagates in the width and thickness direction and the bending resistance of the sheet is significantly reduced. This leads to a drop in the global force level as illustrated in Fig. 2. Shear banding on the compressive side may induce new crack surfaces as shown in Fig. 5. These cracks will, however, not influence the bending resistance since the material is subjected to compressive load.

Fig. 5 The compressive forces may cause intense shear band formation

MATERIAL CHARACTERISTICS

In general, aluminum alloys do not act isotropic in bending but depend on the orientation of the bending axis (BA). An example is shown in Fig. 6 where the same material, in this case an extruded AA6060 alloy with a recrystallized grain structure, shows a large deviation in bendability dependent on the direction of the BA. To the left, with the poorest bendability, the BA is aligned in the same direction as the extrusion direction (ED), and to the right, the BA is perpendicular to the ED. Several microstructural features may affect the bendability and enhance the anisotropic behavior. In the following, the most important aspects will be addressed.

Grain Size and Morphology

Extruded aluminum alloys are typically divided into two classes when it comes to grain morphology: the ones that recrystallize after thermomechanical treatments and those that retain the deformed grain structure. The recrystallized ones gain a more or less equiaxed microstructure with deformation-free grains as shown in Fig. 7a for an AA6060 alloy. The outermost surface layer usually consists of very

Fig. 7 Typical microstructure for heat-treatable aluminum alloys. (a) Recrystallized microstructure and (b) fibrous microstructure with recrystallized surface layer

fine grains, and right below this surface layer, we find the largest grains, which are a bit larger than the rest of the bulk material.^[27,28] The fibrous grain structure, as shown in Fig. 7b, is typically obtained when the alloy contains dispersoids that prevent recrystallization during extrusion. It should be noted that the outermost layer always consists of a recrystallized layer. The thickness of this layer depends on alloy chemistry, die geometry, and processing parameters.^[29–31]

In the finite element simulations presented by Saai et al.^[12] and Mattei et al.,^[32] it is shown that a larger grain size in a material with equiaxed grains leads to an earlier formation of macro shear bands and an increase in surface waviness. In the work by Lievers et al.,^[9] the influence of iron content on the bendability has been investigated. Increasing the amount of iron will, however, not only increase the amount of constituent particles, which was their main intent, but will also influence the grain size, as the increased amount of particles will work as grain refiners. Since these two mechanisms (grain size and particles) counterwork each other, it may be difficult to conclude which of the mechanisms is dominating.

In general, the fibrous alloys seem to have a lower bendability compared to the recrystallized ones.^[8,33,34] For the extruded fibrous alloys, the areas that experience the largest stresses are the surface layer consisting of recrystallized grains, and this may promote surface roughness. In the experimental study by Snilsberg et al.,^[33] a 300 μm layer was removed on both a recrystallized and a fibrous alloy. In both cases, the average bending angle increased slightly, but it was not concluded whether this was a geometrically effect due to sample thinning or due to the removal of the recrystallized layer.

Fig. 8 BA aligned along the seam weld in an AA6082

If the investigated material is taken from a hollow extruded profile, other artifacts from the extrusion process may affect the microstructure and hence the bending behavior. Figure 8 shows the microstructure of a bend AA6082 alloy taken from an extruded profile, where the geometry of the extrusion tool leaves the seam weld on the middle of the wall of the profile. In this case, the BA has been aligned directly along the seam weld. Several authors have looked specifically at the tensile and fracture strength of such seam welds.^[35,36] But not much has been reported directly on the effect of such a mixed microstructure on the bendability. In the work by Snilsberg et al.,^[33] two examples are shown for an AA6060 and an AA7003 alloy, but no clear effect of the extrusion weld on the bending angle was found.

Particles

All commercial aluminum alloys contain constituent particles. These particles are typical Fe-rich phases that form during casting and should not be mixed up with the hardening precipitates that are the definition of the heat-treatable aluminum alloys. Not only is it difficult to avoid Fe in the material, but the constituent particles also play an important role in microstructure control through the thermomechanical process of the alloys,^[37,38] as well as influencing the work-hardening of the material.^[9] The constituent particles are also potent nucleation sites with respect to pore formation and are strongly associated with ductile fracture as described by Benzerga and Leblond.^[39] When Datsko and Yang^[7] came up with the relationship between bendability and RA after tensile testing, this was a purely empirical relationship, but a clear correlation between fracture strain and fraction of constituent particles is also found as shown by Westermann et al.^[40]

The bendability of as-cast materials is poor.^[8,41] From an industrial perspective, formability of cast material is not of significant interest as cast components are directly cast into near final shape. But it is of interest with respect to the understanding of the fracture mechanisms. The constituent

particles in as-cast materials are typically inhomogeneous distributed at the grain boundaries and dendrite boundaries. Marzouk et al.^[41] have shown that the size and shape of the constituent particles in a cast alloy may influence the obtained bending angle significantly. Westermann et al.^[8] showed that the combination of large grain size and distribution of particles along the grain boundaries was detrimental for the bending behavior of the cast and homogenized material, where the crack propagation was similar to the one shown in Fig. 9.

After deformation, either by extrusion or rolling, the constituent particles break up and become smaller, and aligned along the deformation direction like beads on a string.^[42] The alignment of the particles remains unaltered by recrystallization, and such particle constellation is therefore found in both recrystallized and fibrous alloys. Several authors report that particles play a major role in strain localization and fracture propagation,^[1,9,17,43,44] and in the work by Wilkinson et al.,^[10] a clear correlation between the predicted localization and the corresponding particle field is found. When considering the strong effect of the orientation of the BA, as presented in Fig. 6, Westermann et al.^[8] concluded that the alignment of particles, like beads on strings throughout the material, has a detrimental effect on the bendability. The bending angle was in general much lower when the BA was aligned along the ED, and hence in the same direction as the stringers of particles, independent of grain morphology. The crack propagation was found to change from pure shear, when the BA was aligned along the transverse direction (Fig. 10a), to a crack propagating in a zigzag pattern between the stringers of particles with the BA along the ED (Fig. 10b). Davidkov et al.^[17] reported, for a rolled and recrystallized sheet, that the formation of grain boundary precipitates, like β - and Q-phase, played an even stronger role than the constituent particles in the rolled material as they promote intergranular fracture.

Fig. 9 Crack propagation in an as-cast AA7108. Large grains and constituent particles have a detrimental effect on the bending behavior

The heat-treatable alloys do not only contain constituent particles, but they gain their strength from precipitation of small hardening particles. These are much smaller than the constituent particles and form subsequent to hot deformation, either by natural aging or artificial aging at elevated temperatures. These precipitates affect both the yield strength and the work-hardening behavior of the alloy.^[45,46] In the numerical study by Mattei et al.,^[32] it was concluded that large work-hardening parameters lead to lower local strains and decrease the dispersion due to material heterogeneity. The lowest work-hardening parameter is usually observed when the material is in the state of peak hardness.^[46] Nakanishi et al.^[47] reported that the poorest bendability was found in the peak-aged temper, while both the underaged and overaged tempers showed better bending behavior. This is in good agreement with the study by Mattei.^[32] Similarly, Westermann et al.^[8] reported better bendability for the overaged materials compared to the underaged material, for both as-cast, as-extruded, and recrystallized materials. Even though this observation was not directly correlated with the work-hardening parameter, a much larger plastic zone was observed in front of the crack tip in the overaged material, and heterogeneity in the microstructure was found to be the reason for this behavior.

Texture

Texture is usually considered the main cause for anisotropic behavior in the wrought aluminum alloys. Texture is the distribution of crystallographic orientations of a polycrystalline sample, i.e., that some grain orientations are more pronounced after rolling or extrusion. Since many factors influence the mechanical behavior of a material, the effect of texture is more easily cultivated and studied applying crystal plasticity theory, either Taylor-based models (e.g., the works of Kuroda and Tvergaard^[11] and Becker^[48]) or crystal plasticity finite element models.^[12] Dao and Li^[49] concluded that surface roughening (orange peel appearance) works as initiation spots for the shear band formation. The effect of different texture components on shear band formation was systematically studied in the numerical work by Kuroda and Tvergaard,^[11] and a strong effect on shear band formation with strain localization was found especially for the texture

Fig. 10 The crack propagation dependent on the alignment of BA. (a) Pure shear fracture when the BA is aligned along the transverse direction, and (b) shear fracture developing into a zigzag pattern when the BA is aligned along the ED

components related to deformation, i.e., Brass, Copper, Goss, and S. Interestingly, some of these components, i.e., Copper and Goss, seemed to be very dependent on the deformation orientation. The most commonly texture component associated with recrystallization, i.e., the Cube orientation, showed a very homogeneous strain field and was found to significantly enhance the resistance to shear localization independent of orientation. This is in agreement with the experimental work on single crystals performed by Ikawa et al.^[50] This means that a material with a strong Cube texture will show better bendability than one with a weaker texture. In the work by Saai et al.,^[12] a material with a very weak deformation texture (close to random) was investigated, and only a small effect of texture on the shear localization was observed in the simulations, similarly to the observations for random texture found by Kuroda and Tvergaard.^[11]

CONCLUSION

The behavior of the heat-treatable aluminum alloys in three-point bending strongly depends on the microstructure and texture of the alloy. The texture that usually is associated with anisotropic mechanical behavior cannot solely explain the anisotropy observed in bending behavior. The texture, however, plays a major role when it comes to strain localization. In the fibrous alloys, the deformation texture is found to enhance the formation of shear localization leading to earlier failure in the sheet or plate, whereas the Cube texture in the recrystallized alloys improves the bendability significantly. Not only texture leads to strain localization; the grain size also plays an important role, as a larger equiaxed grain size leads to earlier strain localization compared to a smaller grain size. The factor that has the largest effect on the bending behavior, which gives rise to an observed anisotropic difference in bendability, is nevertheless the nonhomogeneous distribution of particles. Constituent particles aligned along stringers change the way the fracture propagates, and the presence of grain boundary precipitates may lead to intergranular fracture.

ACKNOWLEDGMENT

The authors would like to acknowledge Mr. Knut Erik Snilsberg and Ms. Zeinab Sharifi who have worked with this topic in their master theses.

High-Pressure Die-Cast $\text{AlSi}_9\text{Cu}_3(\text{Fe})$ Alloys: Models for Casting Defects and Mechanical Properties

Giulio Timelli

Department of Management and Engineering, University of Padova, Stradella San Nicola 3, Vicenza, 36100, Italy

Abstract

The effect of casting defects on the tensile properties of high-pressure die-cast $\text{AlSi}_9\text{Cu}_3(\text{Fe})$ alloys is reported. A series of U-shaped structural components has been die-cast using a combination of injection parameters and pouring temperatures in order to produce different types and amount of casting defects throughout the casting. The results reveal how the die-castings contain defects, primarily pores and oxides, and their presence and distribution are highly sensitive to the process conditions. The tensile properties are affected by the amount and distribution of defects and can be determined by the defect area fraction. The influence of casting defects on the tensile properties are investigated through a theoretical verification based both on constitutive and stochastic models. The analytical approach, based on the Ghosh constitutive model of tension instability, correctly indicates the trends of the experimental results, while the Weibull statistics evidences how the scale parameter and the Weibull modulus are strongly affected by the casting conditions.

LIST OF SYMBOLS

A_0	Cross section in the sound region of the specimen (m^2)
A_i	Cross section in the defect region of the specimen (m^2)
e_f	Engineering elongation to fracture
E	Young modulus of the alloy (Pa)
f	Area fraction covered by casting defects
i	Ranked position of the specimen strength (or strain) in a set
K	Strength coefficient of the alloy (Pa)
n	Strain hardening exponent
N	Total number of specimens
P_i	Cumulative fraction of specimen failure
Q	Quality index (Pa)
R^2	Coefficient of determination
s_σ	Standard deviation
UTS	Engineering ultimate tensile strength (Pa)
x	Mechanical variable being measured
YS	Yield strength of the alloy (Pa)
α	Scale factor
β	Shape parameter or Weibull modulus
Γ	Gamma function
ϵ_i	True strain inside the defect region
ϵ_h	True strain outside the defect region
ϵ_i^*	Critical true strain of the material in the defect region at fracture

ϵ_h^*	Critical true strain of the material outside the defect region at fracture
$\dot{\epsilon}$	Strain rate (s^{-1})
η	Scale parameter in Weibull statistics
λ	Threshold parameter in Weibull statistics
σ_i	True stress inside the defect region (Pa)
σ_h	True stress outside the defect region (Pa)
σ_f^*	True stress at fracture (Pa)
σ^*	Maximum true stress at fracture of sound material (Pa)
$\bar{\sigma}$	Average fracture stress

INTRODUCTION

The use of light alloys in the automotive industry is, above all, due to the need for decreasing vehicles weight. The same need has to be taken into account in order to face up also both energetic and environmental requirements. In terms of application rates, Al alloys have an advantage over other light materials, such as Mg and Ti alloys. The reduced prices, the recyclability, the increased understanding of design criteria and life prediction for stressed components, and an excellent compromise between mechanical performances and lightness are the key factors for the demand of Al alloys.

A great contribution to the use of Al alloys comes from the improvements in the casting processes, which allow to increase the production, to reduce the cycle time, and to manufacture complex-shaped castings with a thin wall thickness. Among all foundry techniques, the high-pressure diecasting (HPDC) is largely used in the automotive sector because it fulfills the above advantages.^[1]

A limit to large diffusion of HPDC remains the final quality of castings. While the combination of low filling time and high cooling rate gives the possibility of thin-walled castings, the associated turbulence remains the major source of inner and surface casting defects, which have deleterious effects on mechanical properties. In HPDC, if the number of parameters is not adequately determined and adjusted, the quality of the die-cast part results rather poor.^[2,3] Eutectic macrosegregation,^[4] primary intermetallic particles,^[5] and α -Al crystals,^[6] porosity and oxide films, are addressed as typical HPDC defects and microstructural heterogeneities.^[7]

By means of adjusting casting parameters, foundrymen try to restrict and isolate the major part of defects into regions of the casting, which are not mechanically stressed during normal working. Further, thin-walled castings, like those produced by HPDC, are more affected by the presence of defects since a single macrodefect can cover a significant fraction of the cross-section area.

A number of researchers have investigated the influence of casting defects on the mechanical properties both of gravity cast^[8–10] and high-pressure die-cast Al alloys.^[11,12] These works have evidenced how the mechanical properties decrease monotonically with an increase in the area fraction of defects revealed on the fracture surfaces, both of gravity and high-pressure die-cast Al specimens. Even nominally high-integrity castings contain defects; thus, it is important to predict their effect on the mechanical properties.

Several approaches based on through-process modeling for prediction of the structural behavior of high-pressure die-cast Mg and Al alloys' components subjected to static and dynamic loads have been suggested.^[13,14]

On the other side, two different routes based on constitutive models^[15,16] or on statistical and stochastic approaches^[8,17] can be used. The constitutive models are based upon the tensile instability discussed by Ghosh in his analytical approach.^[18] In this model, the tensile strength and deformation of material with internal discontinuities significantly depend upon the fraction of internal discontinuity, the strain rate sensitivity, and the strain-hardening ability.

The effect of structural defects on mechanical properties have also been characterized by Weibull statistics, more specifically, by the two-parameter Weibull modulus.^[17,19] In these studies, the Weibull modulus appears to be a useful measure of the reliability of the casting process. The two-parameter Weibull modulus is extensively used to characterize the tensile properties, especially the tensile

strength. The use of three-parameter Weibull statistics has been explored to illustrate its superior analytical potential over the traditional two-parameter approach.^[20] The three-parameter Weibull analysis provides new information such as the minimum values of strength below which the material is extremely unlikely to fail.

In the study, the influence of casting defects on the tensile properties of the secondary die-cast AlSi₃Cu₃(Fe) alloy was investigated through a systematic experimental approach, with a theoretical verification based on constitutive and stochastic models. Moreover, a combination of injection parameters and pouring temperatures was chosen in order to form different types and amounts of defects throughout the casting.

THEORETICAL BACKGROUND

Constitutive Model of Tension Instability

A porosity or a generic casting defect present in a tensile specimen reduces the load-bearing area. The defective region yields first, concentrating the strain, and the strain hardening ability of the material can indicate the rate of the strain concentration. The formation of an incipient neck can locally occur in the reduced bearing area of the tensile specimen. The growth of this neck can be described using the Ghosh model for the development of plastic instability.^[18] If the neck is not sharp or the strain involved is not large, it may be considered that only one significant stress exists in either the uniform section or the local inhomogeneity.

Fig. 1 A simplified geometry assumed for the development of the model

Source: Reproduced with permission from Cáceres and Selling^[15].

Considering Fig. 1 as a simplified geometry for modelling, which can be assumed to be realistic in a thin-wall die casting, the cross section in the sound region, A_0 , and the cross section in the defect region, A_i , are such that $A_i = A_0(1-f)$, where f is the area fraction covered by casting defects. Under the assumption that the material containing internal discontinuities experiences a tensile load under axial local equilibrium and the effects of strain rate can be neglected, the conventional equation for the stress distribution can be expressed in terms of load carrying area as^[15,18]

$$\sigma_i(1-f)A_0e^{-\varepsilon_i} = \sigma_h A_0 e^{-\varepsilon_h} \quad (1)$$

where σ_i , ε_i and σ_h , ε_h are the true stresses and strains in and outside the defect region, respectively.

A numerical solution of Eq. 1 can be obtained by means of the Hollomon equation^[21]

$$\sigma = K\varepsilon^n \quad (2)$$

where σ and ε are the true stress and plastic strain, respectively, while K is the alloy's strength coefficient and n the strain hardening exponent. The substitution of Eq. 2 into 1 leads to

$$(1-f)e^{-\varepsilon_i}\varepsilon_i^n = e^{-\varepsilon_h}\varepsilon_h^n \quad (3)$$

which relates the strain inside the defect region ε_i to the strain outside ε_h . This relation is shown in Fig. 2 for a

Fig. 2 The relation between the true strains inside and outside the defect region, for area fractions of defects f in the fracture surface between 0% and 30%. Values computed using Eq. 3 assuming n equal to 0.23. The dashed line represents a fracture strain $\varepsilon_i^* = 0.021$ in the defect containing section

material with $n = 0.23$, typically of a die-cast AlSi₉Cu₃(Fe) alloy, and the area fraction of defects f in the range between 0% and 30%. The line for $f = 0$ represents a sound sample for which the strains inside and outside the defect region are equal.

In the present model, it is assumed there exists a critical strain ε_i^* of the material in the defect region at which fracture occurs. Therefore, according to Eq. 3, this assumption implies that, for any given value of f , fracture occurs whenever the strain in the defect region ε_i reaches the critical strain ε_i^* .

Since the true uniform strain of sound material is equivalent to the strain hardening exponent under maximum loading conditions ($\varepsilon_h = \varepsilon = n$), the tensile stress σ_f^* , with a defect content f , can be expressed as

$$\frac{\sigma_f^*}{\sigma^*} = \left(\frac{\varepsilon_h^*}{\varepsilon_h} \right)^n = \left(\frac{\varepsilon_h^*}{n} \right)^n \quad (4)$$

where σ^* and ε_h are the maximum true stress and maximum strain to fracture of sound material, respectively, and ε_h^* is the premature true strain of material which has a defect content f .

Therefore, the predictions of this model depend on the values of n and f , i.e., for a given strain hardening exponent, only the area fraction of defects revealed on the fracture surfaces is important.

Weibull Statistics

Structural defects such as porosity and oxide inclusions or microstructural features such as Si eutectic or intermetallic phases constitute the initiation point of fracture, since they lead to the largest stress concentration. This point will constitute the weakest link, and when the mechanical properties of a group of nominally similar specimens are measured, the data acquired are usually scattered. The statistical distribution that can reasonably model such a distribution was proposed by Weibull^[22] and was originally used to analyze the yield strength and the fatigue behavior of steels.^[23] The common Weibull distribution function is expressed as

$$P_i = 1 - \exp \left[- \left(\frac{x - \lambda}{\eta} \right)^\beta \right] \quad (5)$$

where P_i is the cumulative fraction of specimen failures (e.g., in tensile test), x is the variable being measured (e.g., ultimate tensile strength (UTS) or elongation to fracture), λ is the threshold parameter, i.e., the characteristic stress (or strain) below which no specimen is expected to fail, η is the scale parameter, i.e., the characteristic stress (or strain) at which 63.21% of the specimens has failed, and β is the shape parameter, alternatively referred to as

the *Weibull modulus*.^[8,20,22,23] This configuration of the Weibull distribution is the three-parameter configuration. Generally, for Al castings, the two-parameter form is widely adopted and can be expressed with the threshold value λ taken as zero.

The Weibull distribution is asymmetrical about the mean strength (or strain) if compared to the Gauss distribution. Simplifying Eq. 5 by assuming λ as zero, the Weibull distribution can be converted into the linear form

$$\ln\left\{\ln\left[\frac{1}{1-P_i}\right]\right\} = \beta \ln(x) - \beta \ln(\eta) \quad (6)$$

which can be easily plotted with $\ln(x)$ and $\ln\{\ln[1/(1-P_i)]\}$ as main axes. If the experimental distribution is Weibullian, a straight line will be produced with slope β and intercept $-\beta \ln(\eta)$. The slope β is indicated as a measure of the spread of the distribution.

There are a number of statistical criteria that may be used to estimate the probability of failure P_i , such as the modified Kaplan–Meier method, the Herd–Johnson, and the Benard methods. The most common approach is the median rank approximation, alternatively referred to as the Benard method,^[23] which calculates the failure probability P_i as

$$P_i = \left(\frac{i - 0.3}{N + 0.4} \right) \quad (7)$$

where i is the ranked position of the specimen strength (or strain) in that set, and N is the total number of specimens.

EXPERIMENTAL PROCEDURE

A secondary AlSi₉Cu₃(Fe) cast alloy (EN AB-46000, equivalent to the US designation A380) was supplied as commercial ingots, which were melted in a 500-kg gas-fired crucible furnace and degassed with argon to conform with established foundry practices. Before pouring, the melt was held at $690^\circ\text{C} \pm 5^\circ\text{C}$ for 1 h to ensure homogeneity and dissolution of the present intermetallic. Periodically, the molten metal was manually skimmed and stirred with a coated paddle to avoid any type of sedimentation. The furnace temperature is the holding temperature commonly used for AlSi₉Cu₃(Fe) die-casting alloys, which is enough to avoid the formation of primary Fe-bearing compounds.^[24] The chemical composition, measured on separately poured samples, is shown in Table 1.

Table 1 Chemical composition of the secondary AlSi₉Cu₃(Fe) alloy used (wt%)

Si	Mg	Cu	Fe	Mn	Zn	Ni	Cr	Ti	Al

Fig. 3 U-profile casting with overflows and gating system studied in the present work

The analyzed component was a U-shaped casting with geometry shown in Fig. 3. The U-shaped casting with 2.5 mm thickness was coupled with 5 mm thickness ribs, which are generally locations of high-defect contents in die castings. The weight of the Al alloy die casting was 3.3 kg, including the runners, gating system, and overflows.

The castings were produced in a Müller-Weingarten cold chamber die-casting machine with a locking force of 7.4 MN. A detailed description of the HPDC machine, the casting procedure, and the process parameters is given elsewhere.^[25] Briefly, 10 to 15 castings were scrapped after the start up, to reach a quasi-steady-state temperature in the shot chamber and die. Oil circulation channels in the die served to stabilize the temperature (at $\sim 230^\circ\text{C}$). The fill fraction of the shot chamber, with a 70-mm inner diameter, was kept at 0.56. A combination of injection parameters and pouring temperatures was chosen in order to produce different types and amounts of casting defects. Table 2 summarizes the nominal process parameters set up in the present study.

In the P1 process, the plunger speed was kept constant in the first phase and a rapid acceleration was applied in the second phase, i.e., when the molten metal was estimated to be at the ingate. The same profile was used for the T2 process but the pouring temperature was 50°C lower. In the other shot profiles, the main differences regarded the variation of the commutation point between the first and the second phase: the commutation point was anticipated in the P3 process and postponed in the P2 and P4 processes. Furthermore, the plunger velocity during the fast shot was reduced both in the P3 and P4 injection profiles.

By means of a dynamic shot control system in the HPDC machine, every casting was documented with its shot profile, to monitor the final quality and repeatability. Overall, 235 castings were produced with a cycle time of about 115 s.

Table 2 Nominal process parameters used for producing the U-shaped castings

Process	Plunger velocity slow shot (ms ⁻¹)	Plunger velocity fast shot (ms ⁻¹)	Switch point (mm)	Intensification pressure (MPa)	Pouring temperature (°C)
P1	0.40	3	428	40	690
P2	0.40	3	447	40	690
P3	0.40	2	373	40	690
P4	0.40	2	451	40	690
T2	0.40	3	428	40	640

In order to detect the presence of macrodefects, radiographic inspections were carried out throughout the castings, and the results have been published in.^[25] This type of analysis evidenced how the amount, size, and distribution of defects changed significantly by changing the process parameters during HPDC.

Uniaxial tensile specimens were machined from the wide web, inlet and outlet walls, and ribs of the die-cast U-profiles. Some specimens were machined as aligned with the principal flow direction of the metal during die filling, while others were drawn 90° to the flow direction. Flat tensile specimens were subsequently tensile tested with a crosshead speed of 2 mm min⁻¹ ($\dot{\epsilon} \sim 10^{-3}$ s⁻¹). The strain was measured using a 25-mm extensometer. Experimental data were collected and processed to provide yield stress (YS, actually 0.2% proof stress), engineering UTS, and elongation to fracture (e_f). A total of 160 specimens were tested at room temperature. The values of the engineering ultimate tensile strength and elongation to fracture were then converted to true tensile strength and true elongation to fracture.

Finally, the quality index Q was calculated as^[26]

$$Q = \text{UTS} + 0.4 \cdot K \cdot \log(100 \cdot e_f) \quad (8)$$

where K is the alloy's strength coefficient.

The analysis of the fractured surfaces was carried out using a field emission gun scanning electron microscope (FEG-SEM). The acquired images were then transferred into a single photograph, and the area of defects was quantitatively analyzed using an image analyzer. The total measured defect area on the fracture surface was then divided by the initial cross section of the tensile specimen to find the area fraction covered by casting defects f . In order to study the influence of casting defects on the tensile properties, the previously described constitutive and stochastic approaches were then applied and discussed.

RESULTS AND DISCUSSION

Analysis of Fracture Surfaces

It was found that the U-shaped die castings contained defects, primarily porosity and oxides, and that the

presence and distribution of these defects are highly sensitive to the process conditions. However, variations in defects' distribution were found in castings produced under the same conditions, indicating the stochastic nature of defects in die-castings.^[25] The number of defects revealed on the fracture surfaces varied between only a few and several dozens. In HPDC, the presence of porosity is mainly ascribed to gas entrapment phenomena during the die filling and to the blockage of overflows and vents due to the premature solidification of the molten metal. Generally, the gas pores showed a deformed spherical shape with shiny oxidized surface (Fig. 4a), while oxides appeared as rough regions draping the fracture surface (Fig. 4b). The presence of cold shots was also observed, generally, incorporated within porosity (Fig. 4c).

Contrary, sound specimens revealed a fracture mode predominantly intergranular with regions of cleavage facets, which are visible in the eutectic silicon particles and brittle intermetallic phases, and with zones of deformed and fractured micronecks of α -Al solid solution (Fig. 5). The fracture path follows mainly the interdendritic eutectic zone.

The fracture surfaces of the specimens were almost flat, although a certain degree of tortuosity was present. Therefore, trying to determine exactly if a particular defect was intersected by the fracture plane or the locus of the actual intersection was a rather arbitrary exercise. The determination of area fraction covered by defects was particularly critical for oxides, which were sometimes sitting along the main axis of tensile specimens, as shown in Fig. 6. Thus, it was assumed that all visible defects on the fracture surface lied on a single cross-sectional plane and the projected area were considered for the calculation.

Validation of the Constitutive Model

Considering the same investigated location of the casting, the tensile properties, such as the UTS and the elongation to fracture, showed different values by changing the process parameters; on the other side, the mechanical properties changed throughout the casting under the same applied process conditions. Details of the mechanical properties and quality maps of die-cast components are provided in.^[25]

In general, it was possible to observe how the different amounts of defects revealed on the fracture surface

Fig. 4 FEG-SEM micrographs showing the presence of (a) gas porosity, (b) oxide films and (c) cold shots as revealed on the fracture surfaces

Fig. 5 Typical FEG-SEM view of the fracture surface of sound specimens

Fig. 6 FEG-SEM micrograph of oxide films as revealed on the fracture surface lying almost perpendicular to the fracture plane

influence the tensile properties, such as the tensile strength and the elongation to fracture. Casting defects influence considerably the plastic tensile properties of the material but not the elastic ones. Thus, the Young modulus (E) and the YS were almost steady at 72 GPa and 177 MPa, respectively. In general, the initial yield stress is largely determined by the relatively high supersaturation of atoms (Mg, Cu, Zn and Si) in the α -Al matrix, which is due to the high cooling rate during solidification.

The n and K values were determined by using a double logarithmic plot of the true stress and the true plastic strain, where the n -value represents the slope, and the K -value corresponds to the true stress at a true strain value of unity. No relation between the defect content and the strength coefficient seems to exist, suggesting how the strength coefficient is a matrix-controlled parameter. Cáceres^[26] reported how the strength coefficient relates to the YS and is given as follows:

$$K = \text{YS} \left(\frac{E}{\alpha \cdot \text{YS}} \right)^n \quad (9)$$

where α is a scale factor.

Evaluating the studied alloy in terms of strain hardening exponent, it was observed that the amount of defects does not influence the plastic deformation rate, which is mainly controlled by the microstructural scale, such as the secondary dendrite arms spacing.^[27] The calculated n and K values were steady at 0.23 and 755 MPa, respectively.

As shown in Fig. 7, the true tensile strength of the alloy decreases linearly from 290 to 160 MPa as the area fraction

of defects increases up to about 23%. On the other side, the true elongation to fracture decreases drastically from about 2.1% to 0.3% with an increase in the defect level.

Furthermore, Fig. 7 shows a comparison between the analytical prediction and the experimental results of true tensile strength (Fig. 7a) and true elongation to fracture (Fig. 7b), in terms of variation of defect contents. The true elongation to fracture of the most ductile specimen (ϵ_i^*) was 0.021 (indicated by the dashed line in Fig. 2), and this value was used in the constitutive model to find the maximum homogeneous strain, ϵ_h^* , for the different f values in Eq. 3. The true tensile strength was calculated from Eq. 2 assuming the experimental n and K values ($n = 0.23$, $K = 755$ MPa) and the ϵ_h^* values obtained from Eq. 3. The calculated curves are in good agreement with the trends of the experimental results.

Figure 8 evidences how the quality index of the die-cast AlSi₉Cu₃(Fe) alloy decreases from 370 to 35 MPa almost linearly with the area fraction of defects. In order to model the influence of casting defects on the quality index Q , the values of the engineering ultimate tensile strength and elongation to fracture were first converted to true tensile strength and true plastic strain and substituted into Eq. 10, leading to

$$Q = \frac{(\epsilon_h^*)^n}{\exp(\epsilon_h^*)} + 0.8 \cdot K + \log[\exp(\epsilon_h^*) - 1] \quad (10)$$

which relates Q to the maximum homogeneous strain ϵ_h^* for different f values. The calculated Q values (joined by the solid line) as a function of area fraction of defects are

Fig. 7 (a) True tensile strength and (b) true elongation to fracture as function of the area fraction of defects in the fracture surface. The solid lines represent the calculated curves using the constitutive model of tension instability explained in §2.1

Fig. 8 The Quality Index, Q , as a function of the area fraction of defects in the fracture surface. The solid line represents the calculated curve obtained according to Eq. 10

compared with the experimental results given in Fig. 8. The calculated curve correctly indicates, yet again, the trend of the experimental data.

The results shown in Figs. 7 and 8 indicate how the area fraction of defects evaluated in the fracture surface is a reliable parameter to predict the tensile properties of the die-cast AlSi₉Cu₃(Fe) alloy, despite some scatter in the data. The results are in good agreement with the analytical approach based on the Ghosh constitutive model.

The scatter observed in the experimental data can be considered related to the fracture behavior of the material.^[15] Some imperfections are always present even in sound specimens, and they tend to produce some vertical scatter both in the tensile strength and ductility.

The source of horizontal scatter arises from two main factors. First, the measurements of the defect size are difficult to be precisely determined since the boundaries of defects are often shaded and not well defined. Secondly, the casting defects do not always lie on the same cross-section fracture plane, especially oxides (see Fig. 6); thus, the projected area used to calculate f may not be correctly estimated with respect to the real defect area fraction.

Several works^[10,28,29] suggested that the morphology and the distribution of defects are important factors controlling the final mechanical properties. Thus, there is the possibility that some of the scatter can be attributed to these causes too.

Die-cast AlSi₉Cu₃(Fe) alloy specimens with an area fraction of defects higher than 0.25 present a brittle fracture well below the yield point. This means that the strain concentration in the defective region produces a very great damage in the specimen, causing the premature fracture of the material.

Application of Weibull Statistics

The engineering tensile strength and elongation to fracture data obtained from the U-shaped castings produced with the different process parameters were statistically analyzed using both the Gauss and the two-parameter Weibull models. The goodness of the relation for each

Fig. 9 Weibull plots for UTS and elongation to fracture obtained from different casting processes; the diameter of the bubble is proportional to the area fraction of defects f

statistical distribution was evaluated by the modified Anderson–Darling test. The test statistics for each model showed that the fitted distribution could not be rejected. In general, the correlation coefficient of the Weibull distributions calculated for the different processes was higher than 0.98, while it was about 0.95 considering the Gauss distributions. This makes the use of the Weibull statistical approach as reliable.

Figure 9 shows the corresponding linear Weibull plots where the diameter of the bubbles is proportional to the area fraction of defects f evaluated in the fracture surface of each tensile specimen. While lower values in the two-parameter Weibull plots represent the specimens with higher f values, the diameter of the bubbles seems to decrease along straight lines. Therefore, the probability of failure P_i increases by increasing the defect content f , indicating the fundamental role of defects in fracture mechanism.

Table 3 shows the quantitative results of the Weibull analysis of the die-cast AlSi₉Cu₃(Fe) alloy with different process parameters. It is evident how the β and η values for the two-parameter fits are strongly affected by the casting parameters used. It is observed how the Weibull modulus is around 10 or lower, while for many gravity-filled castings this is generally between 10 and 30; for good-quality aerospace castings a value between 50 and 100 is usual.^[30] The various slopes correspond to different distributions of casting defects, such as pores, oxide, and cold shots.

The variation in the injection profiles, as done from P1 through P4 processes, caused the Weibull moduli to decrease. Furthermore, the reduction of the casting temperature from 690°C to 640°C in the P1 process leads also to a decrease of the Weibull moduli for the UTS (6.5) and elongation to fracture (2.5). The minimum β values were reached by using the P4 process. This means that reducing the plunger velocity during the fast shot and simultaneously delaying the commutation point between the first and the second phase clearly decreases the reliability of the castings. If the first metal that flows into the cavity is slow because the plunger is still accelerating to fast shot, then this metal will have the tendency to splatter or run into the cavity at low velocity. Thus, the molten metal rapidly solidifies as a solid layer on the die surface, and it is covered by an oxide film due to the air contact inside the die cavity.

The rest of metal flowing into the cavity during the filling stage will lay on top of the first layer and will not remelt it. This condition leads generally to a discontinuity inside the solid component.

In general, the mechanical values and the highest tensile properties obtained in the present work are well below the *potential tensile properties* attainable for die-cast AlSi₉Cu₃(Fe) alloys. Gunasegaram et al.^[31] and Timelli et al.^[32] evidenced how AlSi₉Cu₃(Fe)-type alloys can reach values of about 320 MPa for UTS and 4% as elongation to fracture, if the defect content is significantly reduced. This evidences even more the key role of casting defects in controlling the mechanical behavior of die castings.

Tiryakioğlu and Campbell^[20] observed how in a two-parameter Weibull plot there exists a threshold stress λ below which failure would not occur, suggesting that three-parameter Weibull analysis would be more appropriate. When λ is taken as zero, as in the two-parameter fits, there is a probability that the fracture stress of specimens will be less than the yield stress, even if the specimen has reached and deformed plastically beyond the yield stress. It is important to underline that in the two-parameter Weibull model, the ratio of the average to the standard deviation is a function only of β and can be given as follows:

$$\frac{\bar{\sigma}}{s_{\sigma}} = \frac{\Gamma\left(1 + \frac{1}{\beta}\right)}{\sqrt{\Gamma\left(1 + \frac{2}{\beta}\right) - \left(\Gamma\left(1 + \frac{1}{\beta}\right)\right)^2}} \quad (11)$$

where $\bar{\sigma}$ is the average fracture stress, s_{σ} is the standard deviation, and Γ represents the gamma function. Increases in the average or decreases in the standard deviation increase the value of the Weibull modulus. Hence, higher β does not necessarily mean higher repeatability or reliability.^[20,30]

Therefore, the increase in β value observed by changing HPDC process parameters and the use of two-parameter Weibull statistics can be considered as an “increase in safety” more than an “increase in reliability”, because it would indicate an increase in the threshold stress or ductility if three-parameter Weibull statistics were used.

Table 3 Weibull moduli, β , and scale parameters, η , for engineering UTS and elongation to fracture; the coefficients of determination, R^2 , are given

Process	UTS			e_f		
	β	η (MPa)	R^2	β	η (%)	R^2
P1	9.7	249	0.98	3.5	1.1	0.98
P2	6.6	257	0.98	2.5	1.3	0.98
P3	11.6	229	0.98	3.5	1.0	0.99
P4	6.0	243	0.99	1.9	1.2	0.99
T2	6.6	243	0.98	2.4	1.2	0.99

CONCLUSIONS

The influence of casting defects on mechanical properties of a high-pressure die-cast AlSi₉Cu₃(Fe) alloy has been investigated through an experimental approach, with a theoretical verification based on analytical and statistical models. The following conclusions can be drawn:

- Components die-cast with a combination of different injection parameters and pouring temperature show casting defects mainly in the form of porosity and oxides.
- The presence and distribution of defects are highly sensitive to the process conditions.
- The different types and amounts of defects influence considerably the plastic tensile properties of the material, such as the ultimate tensile strength and the elongation to fracture, but not the elastic properties.
- The analytical approach based on the constitutive model of tension instability correctly indicates the trends of the experimental results.
- The Weibull statistics evidences how the scale parameter η and the Weibull modulus β are strongly affected by the die-casting parameters and therefore by the overall amount of defects.

High-Speed Computer Tomography: Pressure Die Casting

Christian Heikel

Faculty of Mechanical Engineering, University of Applied Science – Ostfalia, Salzdahlumer Str. 46–48, Wolfenbuettel, 38302, Germany

Eberhard Ambos

University of Magdeburg, Magdeburg, Germany

Abstract

For many years, molders have been trying to figure out the influence of diverse factors on the quality of die castings during molding. In 2010, the rapid computer tomograph became available for the first time. This system is derived from medical technology and offers new testing methods. The measures, which have been in progress for the past 5 years, were focused to point out the correlation between the major influences of pore expression in pressure die castings. These results are suggestive of the future technological and constructive work. Through continuous improvements in testing methods, the technology finally succeeded to work out major influences on pore expressions in pressure die castings. With these new findings, it is possible, and even proven by example, that through the right choice of process parameters strength-influencing pores can be reduced. In case of not preventing the formation of pores, they could be moved out of the areas, which are strength vulnerable. This is an appropriate concept to reduce the weight of components and therefore the implementation of lightweight constructions in the automotive industry.

Keywords: Casting porosity; Casting quality; Computer tomography; Die casting.

INTRODUCTION

At the end of 2005, a new trend developed in the automotive industry, which continues until today. Simple and small castings are being replaced by bigger, more complex parts. Therefore, new material testing methods are needed to examine these intricate components. One procedure meeting modern needs is the rapid computer tomography (CT). With this technique, not only can single components be examined, but large-scale productions as well.

Figure 1 shows three small castings being composed into one large casting. The shown part is called “lower part of the gearbox housing”. The three smaller parts weigh 396 g, 412 g, and 1764 g. The new compound casting substitutes the single parts and has a weight of 2666 g (Fig. 2). The increase in complexity is also apparent in the increase in volume. The enclosed volume of the single parts 0.5, 0.5, and 3.5 L sums up to a total of 7 L for the complex part. The expression “enclosed volume” describes the volume that is created by the outer encasement or the housing of the component. In this regard, it is important to know that the volume inside the component is made up of aluminum and major cavities. In other words, the enclosed volume does not correlate with the weight of the component. However, the enclosed volume is important to describe the complexity of the molding geometry and the flow pass of the metal.

To cast the new component is more complex, but it includes more technical functions. Additionally, the assembly effort is reduced.

The described trend toward bigger and more complex components is typical for cast components in the automotive industry. Logically, this trend results in more stringent requirements regarding the casting technique. Figure 3 shows the flow path of liquid metal during molding. It can be seen that along with the flow path the mass of the transported material increases as well.

There are also vast changes regarding the heat dissipation inside the mold, shown in Fig. 4. As can be seen in the figure, the construction of the component and the construction of the mold are not chosen optimally. Areas, called Hotspots, can be identified. Hotspots are critical areas, which solidify toward the end of the casting process. These Hotspots can lead to blowholes.

Another problem is the dissipation of gases during the casting process. It is no secret that these reoccurring errors of modern and complex casts present a problem for the production. Pores and blowholes often result in leaking components.

To avoid the development of pores and blowholes, different options for cooling and evacuation of the mold were examined. To ensure that the quality requirements are being met, rapid CT was used. For the first time, it was possible to build a statistic of the location and size of pores

Fig. 1 Integration of three small casting parts into a complex single part “lower part of the gearbox housing”
Source: Druckguss Heidenau Germany and GiessereiPraxis Germany 2016.

Important remark: The enclosed volume describes the volume that is created by the housing of the component. The enclosed volume contains aluminum and also air cavities.

and blowholes by examining a large number of components. In the past, it had only been possible to examine single parts in selected areas.

The results are described in the following sections.

METHODOLOGY OF TESTS AND RESULTS

It is a matter of common knowledge that the production influences on the quality of die castings can be very complicated. Multiple references can be found in the literature.^[1–2] Until the start of this study, the main influences had not been identified. Therefore, the research presented in this article was not conducted only in a laboratory. To be able to take all production influences into account, die castings from real factory productions were being examined. Figure 5 illustrates this procedure.

To obtain a comprehensive analysis, the aim was to document as many production parameters as possible; hence all die casting machines were fitted with sensors. The test components got marked directly after the extraction from the die casting machine. The markings contain information about the date of production and the machine being used. After that, the die castings were examined for volume deficits (pores and blowholes) with a rapid CT. That way, each casting can be connected to its production parameters.

As already mentioned, by using CT, it is now possible to examine die castings on a much larger scale. In previous researches, only single components or samples were studied. Now 100 components or more can be tomographed. The evaluation of the obtained data focused on the statistical distribution of pores, not on the individual defects. Table 1 gives an overview about the test data.

The sensors in the die casting machine collect a variety of data. The vacuum inside the mold, the temperatures of the mold, and the amount of release agent were measured and documented. Figures 6–8 show all significant tests of the past years.

The research was achieved through outstanding teamwork. The team consisted of scientists, experts of casting

technique and mold construction, and operators of the casting units. In addition, computer experts were needed to evaluate the tomograms.

The results were discussed at several conferences with further experts.

DEVELOPMENT STEPS OF THE RAPID CT AND THEIR SOFTWARE

The research was conducted in close cooperation with the creators of the CT systems. The results of this work also influenced further developments of the systems.

At the beginning of this study, the aim was to integrate the CT systems into the manufacturing line. This idea was discarded due to financial reasons. The CT systems are now being used for numerous casting units in the manufacturing process, for the run-up and restart.

For the usage in a line production, the CT systems were improved and the supply and pickup of castings were optimized. There are two different ways to pick up castings:

- A measuring probe rotates around the component, and the component is supplied, for example, by a conveyor belt.

- The component is rotated in front of the radiation source.

MAIN CONCLUSIONS OF THE STUDY

Figures 6–8 give an overview of all conducted tests. The initial tests are characterized by a steep learning curve. Training was vital for the new technology and various disciplines needed to work together. This task has only been possible because of the outstanding cooperation of the entire team.

The research started in 2011 on the component “Console”. The most important finding is the substantial difference between calculated pores and pores detected by the CT systems. The computer simulation predicts a too high porosity. Furthermore, the computer simulation (Fig. 9a,b) only gives a rough indication about the position of casting defects. The tomogram, on the other hand, shows the actual position of pores and even the pore volume. However, major defects can be detected accurately by using the simulation.

In the initial tests, parameters for the die casting process were not yet documented, and the inspected quantities were small. When it became evident that the position of defects was subject to scattering, further measurements

Year of research	Examined die-castings	Specific objectives for the tests
2014	Pedestal of high-pressure-pump 	-First-time adoption of a multiform for highly stressed die-castings. -Evaluation of various trimming-systems under similar technological conditions on the characteristics of pores inside the die-castings. -Acquisition of further influencing variables. -Comparison of molding results between “old” and “new” die-casting machines. -Calculation of correlation coefficient among the porosity and all technological influencing variables that were collected. -Collecting all extreme values of porosity and comparing them with values for the individual four “nests”. -Comparison between various CT’s for identical die-castings.
2015	Engine pedestal 	-Testing of various ventilation systems on the position and volume of porosity. -Initial comparison between anticipated die-casting strengths, under consideration of the pore volume, and measured statistical strength values. -Complete acquisition of technological influencing variables and pore volumes as well as a calculation of valid correlation values. -Acquisition of influences regarding the election of appropriate casting-alloys as well as the thermal treatment on achievable strength properties.

were carried out to determine a more accurate exploration of scattering pores. In addition, the manufacturing parameters were considered.

Another component, which was inspected and analyzed in numerous experiments in 2011, was the “gearbox housing-lower part”. This component is the complex part described at the beginning of this article. Figure 10 shows the influence of ventilation (evacuation) in the molding on the porosity. There are four ways of ventilation.

Variant A1 is the initial variant: ventilation via chill bodies with a piston speed of 0.1 m/s. Method A1 results in a high porosity (left bars)—average volume of pores 45.19 mm³.

Variant A2: ventilation via chill bodies with a piston speed of 0.05 m/s. This variant shows the least casting defects (middle left bars)—average volume of pores 19.45 mm³.

Variant B2 includes an additional step—extraction of the gas at the filling chamber (middle right bars)—average volume of pores 24.45 mm³.

Variant C2: includes an additional step—extraction of the gas at the die casting mold and filling chamber (right bars)—average volume of pores 30.61 mm³.

The quality of the initial variant A1 was improved by all three variants, stating that all three variants lead to lower levels of porosity. Thus, the improvement of the casting process was verified effortlessly by the new testing method. Figure 11 shows the two-dimensional distribution of defects.

In 2012, another component, the “mount ancillary-component,” was studied. This component is characterized by being produced in large quantities on numerous casting molds and needing a monthly start-up. Due to numerous start-up problems, technological measures were needed to optimize the manufacturing process. Temperature influences and the evacuation of the mold were improved to prevent the formation of pores close to areas where a machining process was planned to take place.

Just like the other components, the “mount ancillary-component” showed significant differences in

Fig. 10 Influence of evacuation in the molding on the porosity by four different ways of ventilation

Source: University of Applied Science Magdeburg and GiessereiPraxis Germany 2016.

simulated and measured pore scatterings. Thus, it became mandatory to reduce pores by evacuating the casting mold. This was possible by using chill bodies. The decrease in porosity is shown in Fig. 12. The difference in defects after the technological improvement is clearly visible.^[4]

While in 2011 and 2012 experiences were gained with this new testing technique, in 2013 the scientific research was deepened. For the first time, a comprehensive examination of manufacturing parameters was conducted. The component “mount ancillary-component” was manufactured using the die casting machine “GKU Evolution B 84 DV”.

With the support of software experts of the company Volume Graphics GmbH, based in Heidelberg, Germany, it was possible to study defined positions of the component in detail. Figure 13 shows one die casting part and the areas of special interest.

Four series of tests were conducted:

Series 1: Same parameters as of those from prior manufacturing periods.

Series 2A: Parameters as used in series 1, with an additional “Jet Cooling-Core” with longer cooling times.

Series 2B: Parameters as used in 2A, with shortened cooling time of the “Jet Cooling-Core”.

Series 3: Parameters as used in 1. Mold-temperature-regulation lowered from 180°C to 100°C.

In total, 163 components were examined in the introduced four test series. The results of the test are presented later.^[5]

Within the individual test series, severe fluctuations of porosity were observed. Test series 1, for example, shows a minimum value of 0.0197% and a maximum value of 0.1954% resulting in a range/span by the factor 10. Figure 14 shows the comparison of minimal and maximal porosity.

The porosity decreased due to better cooling (Test series 2A—Jet Cooling) (Table 3).

Regarding the impermeability of the components, not only the volume of pores but also the position of pores is of interest. Therefore, despite a bigger pore volume, components of test series A was considered impervious to fluids. Whereas test series 2B featured two leaking components (Figs. 15 and 16).

In the future, a rapid CT should examine complex die castings before undergoing a cost-intensive machining process. Thereby additional work can be prevented.

The study has shown that adjustments to the molding parameters influence the development of pores significantly, Table 2.

First, relations between molding parameters and porosity were identified (Fig. 17).

In 2013, further tests were conducted on the components “steering-gear-housing” and “valve bodies for

Table 2 Porosity of the experimental series 1, 2A, 2B, and 3

automatic transmissions” (Fig. 7). The lowest pore values, with 0.009% per component, were achieved by optimizing cooling with Jet Cooling-Cores^[6] in production of the component “valve bodies for automatic transmissions”.

These tests were continued systematically in 2014. The targets of these tests are shown in Fig. 8. The focus of these tests was on the comparison between an old and a completely new die casting machine. An identical casting mold was used

Fig. 14 Comparison of porosity of two castings: (a) minimum, (b) maximum

in both machines. The following hypothesis was proposed before the tests: The new machine produces significantly better results. Figure 18 shows the manufactured components “pedestal high-pressure pump” in one molding/cast.

Three series of tests were conducted:

Series 1: 100 mold fillings (this is equivalent to 400 casting components) on the older machine; Type Bühler GKU Evolution B 84V, year of construction 2007.

Series 2: 100 mold fillings on the new machine; Bühler Evolution 90 compact, year of construction 2014.
 Series 3: 3 shots with 12 parts “pedestal high-pressure pump” with modified trim-system.

Series 1: There is an accumulation of pores that lies between a maximum of 0.33% and a minimum of 1.05% per part (Fig. 19). The average porosity is summarized in Table 3. The form includes four parts per molding, which are called nests. The parts of nest 4 show the lowest levels of porosity.

Fig. 17 Porosity depending on the plunger speed. Increased porosity at a speed of >4.45 m/s

Fig. 19 Transparent view of the components “pedestal high-pressure pump”: (a) minimal porosity (0.33%) and (b) maximal porosity (1.05%)

Source: University of Magdeburg and GiessereiPraxis Germany 2016.

No mathematical correlation between porosity and molding parameters was verified after evaluating series 1 (Fig. 20). The tests performed on the new pressure die casting equipment, series 2, showed no significant improvements. Table 3 illustrates that in both series the priorities in nest 3 & 4 reach extrema.

The measurement results, that are highlighted by a circle (Fig. 21), demonstrated a sample test with 12 parts. The sprue of the form has been changed here. It is recognizable that these actions had a big influence on the casting quality. The correlation between casting parameters and porosity has been calculated.

Following the conclusions of measurements from 2014 that had been drawn from continuing tasks,^[7] it must be further examined whether there are correlations for the manifestations of pores or not.

The test series 3 indicate that the porosity can be positively influenced by small adjustments on the sprue of the casting. By using a rapid CT, a good compliance in quality was reached. However, it is important to use the same CT with consistent software.

Source: GiessereiPraxis Germany 2016.

In 2015, another interesting die casting (“Engine-Pedestal”) was available for examinations (Fig. 22). This cast represents highly stressed parts that are developed to the optimum level.

The experiences gained from previous tests were implemented to subsequent experiments, and the tests were prepared intensively by the team (designers, simulation experts, flow experts, production planners). This enabled a smooth study of the first casting test.

All castings were screened by a computer tomograph (Company Carl Zeiss in Oberkochen, Germany). Figure 23 shows a part inserted in a CT.

Components of this test series showed familiar fluctuations of porosity, which can be seen in Fig. 24. The extreme values should be noted. It must be mentioned that molding parameters were optimized during the first test, resulting in a porosity reduction. Outliers (marked with numbers) seen in this diagram can be explained by unwanted adjustments in the molding process. The main reasons leading to these outliers are too low molding pressures and mold remainder heights. Boundary parts with minimum and maximum levels of porosity are shown in Fig. 25. Figure 26 shows the relation between mold remainder heights and pore volumes.

Due to the intensive experimental procedure, it was possible to detect increased correlation values between porosity and individual process parameters. Table 4 shows the following correlating influences: mold remainder heights, casting pressure, end of mold filling, and metal trim switchover

point reached. A value of >0.5 signifies that the influence on the porosity is rated with 50%. This finding represents a milestone in researching the die casting process.

After test series 1, work continued by decreasing the pores. In this case, the ventilation system was examined. Additional ventilation channels were used, and valves were integrated for ventilation and evacuation. All these measures were conducted on the same form used in test series 1. Figure 27 shows the improvements achieved with the taken measures. The first test series, “11.3.2015,” showed an average porosity of 0.617%. The second test series, “25.6.2015,” reached a value of 0.406%.

Fig. 25 Transparent illustration of the component “engine-pedestal”: left: component-No. 73 with least levels of porosity with 0.33%; right: component-No. 79 with highest levels of porosity with 3.93%

Source: Volumegraphics Heidelberg and GiessereiPraxis Germany 2016.

The levels of porosity were of interest for the experiments, because pores accumulate in areas of high mechanical stress levels (see cover). The figure shows the “engine-pedestal” pores in areas of highest stress, which are colored red (bottom right). To minimize the weakening influence of the pores, the aim was to reduce the pores in areas of high mechanical stress.

Finally, Fig. 28 shows an overview of the most important results.

FINDINGS AND CONCLUSION

Until today, the die casting process is frequently optimized empirically, even though a big growth in knowledge has

Fig. 26 Porosity in dependence of the “mold remainder thickness”

Source: University of Magdeburg and GiessereiPraxis Germany 2016.

Fig. 27 Comparison of the porosity of two different casting experiments “engine-pedestal” 11.3.2015 and 25.6.2015

taken place. Most of the die-casters calculate the manufacturing process with qualified computer simulations. Nevertheless, after the computer simulations nearly all die castings are being improved by an empirical touch-up of process variables. In the future, due to the increasing digitalization, a lot of follow-up research work is necessary.

To sum up, this article shows that the rapid CT offers great potential as a test device for challenging examinations. Soon, a systematical use of rapid CT's is expected to contribute to a fast evolution of computer simulations, provided that all process parameters will be recorded and documented at the foundry. This of course applies to the tomograms as well. These parameter and tomograms are also useful for an eventual restart-up of die castings. Databases for tomogram-evaluation already exist in medical technology.

Automobile components will be lighter in the future. In addition, the components must be more stress resistant. Therefore, the CT technology will be an indispensable test medium regarding development and quality assurance.

Abstract

Cast aluminum alloys find widespread application in the automotive and aircraft industries on account of their good castability, corrosion resistance, and high strength to weight ratio. Use of quality indices to rank cast aluminum alloys in terms of their quality has been in vogue since 1980s. Quality indices enable design engineers to select appropriate alloy condition by comparing the changes in quality with the changes in processing parameters like aging temperature and aging time. They also enable design engineers to select an appropriate alloy by way of comparing the quality obtainable with different alloy compositions. The present article highlights the effect of hot isostatic pressing (Hipping) on the quality of cast aluminum alloy 354 by using quality indices Q_0 , Q , and Q_c put forth in published literature. It has been observed that material in Hipped condition has higher value of these indices as compared to non-Hipped condition. This behavior is consistent across different aging conditions of the alloy. It is concluded that improvement accruing through Hipping of cast aluminum alloy 354 can be satisfactorily rated by using these quality indices.

Keywords: Aging treatment; Cast aluminum alloys; Hipping; Mechanical properties; Quality index.

INTRODUCTION

Engineers in the automotive and aircraft industries work within an ecosystem that often places competing demands in the context of designing components with optimum weight and high performance. Cast aluminum alloys have become materials of choice in these industry segments owing importantly to their high strength to weight ratio. Alloying elements have an important role to play toward improving the performance of cast aluminum alloys. The contribution of different alloying elements toward improving the performance levels of cast aluminum alloys has been discussed in detail in the *Handbook of Aluminum*.^[1] There are several grades of cast aluminum alloys commercially available. The three-digit designation for cast aluminum alloys has found wide acceptance, and the same is used in this manuscript to refer to different grades of cast aluminum alloys. The alloy 354 is one of the prominent grades; it is based on the Al–Si–Cu–Mg system. It has become an important industrial material owing to its excellent mechanical properties and good castability. It finds widespread use in the manufacture of compressor wheel castings. The studies reported here are primarily based on the work carried out on this alloy.

Quality of aluminum alloy castings is a matter of constant concern for the design engineers. The castings suffer from solidification defects like gas holes and shrinkage cavities. These defects adversely affect the reliability of the final component. For example, Yi et al. reported that porosity was invariably observed to be major crack nucleating defect in A356-T6 castings.^[2] Shivkumar et al. concluded that porosity in aluminum alloy castings has a strong influence on fracture and fatigue life.^[3] Casting defects lead to not only reduced values of mechanical properties but also high scatter of these properties.^[4,5] This is considered unsuitable for industries that place strict demands on component performance.

Significant advances have been made to improve the quality of cast aluminum alloys using different processing techniques, hot isostatic pressing (Hipping) being an important development among them. Hipping is the process of subjecting a component simultaneously to both elevated temperature and isostatic pressure in a controlled environment. Hipping is known to substantially eliminate microporosity resulting from the precipitation of hydrogen and the internal shrinkage occurring during solidification. The technology of Hipping—equipment, process, and benefits accruing—is covered in the immediately following

section. The benefits accruing from Hipping of different grades of cast aluminum alloys are briefly reviewed in Section “Benefits Accruing from Hipping.”

Comparative evaluation of quality indices Q_0 , Q , and Q_c was carried out in Hipped and non-Hipped conditions for castings of alloy 354 over a range of aging conditions. All three indices show an increase after Hipping, indicating that they are suitable to rate the improvement in quality resulting from Hipping.

TECHNOLOGY OF HOT ISOSTATIC PRESSING (HIPPING)

Introduction

Hot isostatic pressing (Hipping) has been made use of in multiple ways—consolidating powders, densifying presintered components, upgrading castings, etc. Both metallic and ceramic materials have been processed by Hipping. Treatment of Hipping in this section will be with emphasis on upgradation of aluminum alloy castings. For a detailed discussion of Hipping—equipment, process, application as a production means for a wide spectrum of metallic, ceramic, and composite materials—attention of the reader is drawn to.^[6–11] Details appearing in this section have been largely drawn from the same set of references.

In the Hipping process, the component is subjected to a combination of high pressure and elevated temperature. Isostatic pressing is what occurs in Hipping, in that the pressure is the same all over the surface of the component and acts in a direction normal to the surface. Isostatic pressing is to be distinguished from the more conventional unidirectional pressing. Isostatic nature of pressing in Hipping allows the shape to be maintained; it also leads to total void removal. In contrast, unidirectional pressing cannot maintain the shape nor can it fully remove internal voids. The temperatures for Hipping are usually greater than 0.7 times the melting point. For example, the Hipping temperature for cast aluminum alloys is typically of the order of 500°.

In the context of cast aluminum alloys, Hipping is largely concerned with the removal of pores. Pores may originate from gas evolution or shrinkage during solidification of castings. The reduction in surface energy of the pores is the driving force for achieving densification.

Equipment and Processing

Hipping is performed inside an insulated pressure chamber with provisions for heating, pressurization piping, and instrumentation. The equipment for pressurization and process control is external to the pressure vessel. Figure 1 shows schematically the setup for Hipping. The high-pressure chamber is a major component of the equipment. The heating arrangement is for taking the stock to the desired temperature. Heat transfer to the stock is mostly

Fig. 1 Schematic representation of the hot isostatic pressing

by convection and radiation. Argon and to a lesser extent helium are used for transmitting pressure. Inert gas is used so that oxidation/nitriding of component surfaces and chamber walls does not occur.

After loading the components in place and sealing the chamber, the chamber is evacuated and then filled with inert gas. Pressure of the gas is increased to the value specified by the application in hand. Typical pressures are in the range 103–207 MPa. The temperature inside the chamber is simultaneously increased to the desired value. Dwell times under the combination of specified pressure and temperature are typically in the range 2–6 h.

The elevated temperature leads to a lowering of yield strength. Under the influence of applied isostatic gas pressure, stress concentrations occur at the void boundaries. Localized time-independent and time-dependent plastic deformation takes place leading to void collapse, surfaces of voids coming in contact, diffusion bonding, and completion of the healing process.

Hipping temperature is selected to keep the deleterious effects at bay—incipient melting, coarsening of dispersed phase/precipitate, and grain growth. The selection of temperature for cast aluminum alloys is also based on the temperature used for the ensuing solution treatment.

Benefits Accruing from Hipping

Published literature indicates that Hipping is a production process that can improve the quality of cast components. Extracted from^[12] and listed below are the benefits of Hipping for the case of cast components:

- Eliminates porosity.
- Improves fatigue properties.

- Improves creep properties.
- Improves ductility and impact strength.
- Decreases scatter of properties.
- Enables recovery of defective parts.
- Creates material savings.

DIFFERENT QUALITY INDICES PROPOSED BY RESEARCHERS

Quality Index Q

Drouzy et al. from France were the first to propose a quality index for cast aluminum alloys based on results obtained in a tensile test.^[13] They proposed the empirically derived quality index Q that covers ultimate tensile strength and the elongation at fracture for the case of Al–Si–Mg alloys.^[13] The quality index Q was defined as

$$Q = R_m + d \cdot \log(A_f), \quad (1)$$

where R_m is the ultimate tensile strength, A_f is elongation to fracture, and d is an alloy-dependent coefficient.

Quality Index Q_R

While Q has been successful in representing the quality of Al–Si–Mg alloy system, it did not lend itself easily to describe the behavior of Al–Cu alloys. The Q produced loops on the R_m versus A_f diagram, instead of straight lines.^[14–16] As a result, another quality index Q_R was introduced by Din et al.^[14] Q_R is also based on the experimentally measured values and it can be given as follows:

$$Q_R = R_p + m \cdot A_f, \quad (2)$$

where R_p is the yield strength, m is an alloy-dependent constant, and A_f is the elongation to fracture.

Quality Index Q_C

Caceres^[17] introduced the quality index Q_C . Analytical model for Q_C has been presented in.^[17–19] The quality index Q_C has been defined as a function of the yield strength R_p of the material:

$$Q_C = R_m + 0.4 \cdot R_p \cdot \left(\frac{E}{a \cdot R_p} \right)^n \cdot \log_{10}(A_f). \quad (3)$$

Quality Index Q_0

Alexopoulos and Pantelakis^[20] defined the quality index Q_0 as a measure of the mechanical performance of cast aluminum alloys. Q_0 takes into account both strength and toughness of the alloy. The strength of the alloy is represented by yield strength R_p and the toughness is represented by the strain energy density W .^[20] The strain energy density W is

evaluated using the area under the true stress–true strain curve, which can be defined as follows:

$$W = \frac{dU}{dV} = \int_0^A \sigma \cdot d\epsilon, \quad (4)$$

where U is the strain energy, V is the material volume, and A is tensile elongation to fracture. It is expressed in units of MJ/m³. Figure 2 illustrates calculation of W from the stress–strain curve. Q_0 is a function of yield strength R_p and strain energy density W :

$$Q_0 = R_p + 10 \cdot W. \quad (5)$$

The number 10 appearing in the expression for Q_0 represents a typical value of the ratio of R_p/W for properly optimized advanced aluminum alloys.^[20]

The yield strength R_p was used by the researchers instead of ultimate tensile strength R_m based on the consideration that any aircraft industry operates in an environment that does not tolerate high amounts of yielding of the material due to the close mechanical tolerances between components. At the same time, strain energy density W has been preferred over elongation to fracture A_f because W captures the entire elastic and plastic range of material's operation instead of just representing the elongation to fracture.

To take into account the scatter in the tensile properties of material, Alexopoulos and Pantelakis^[20] proceed to define quality index Q_D using the following equation:

$$Q_D = K_D Q_0, \quad (6)$$

where K_D is dimensionless factor.

Quality Index Q_E

Tiryakioglu et al.^[21] proposed the quality index Q_E given by the following equation:

Fig. 2 Calculation of strain energy density W of the sample from the true stress–strain curve obtained from tensile test of the specimen

$$Q_E = W / W_c, \quad (7)$$

where W is the strain energy density of the material and W_c is a fixed value of strain energy density of the ideal material with no structural discontinuities.

The index is based on the concept that energy absorbed is directly related to the effective crack length produced by discontinuity.

Quality Index Q_T

Tiryakioglu et al.^[22] proposed the quality index Q_T given by the following equation:

$$Q_T = \frac{e_F}{\beta_2 - \beta_3 \sigma_Y}, \quad (8)$$

where e_F =elongation to fracture (%), β_2 =an empirical constant, β_3 =an empirical constant (MPa^{-1}), and σ_Y =Yield strength (MPa).

A comprehensive discussion of the relative merits and demerits of different quality indices proposed by researchers in the past is not within the purview of this paper. The reader is referred to Alexopoulos^[23,24] and Tiryakioglu et al.^[22] for a critical discussion of the use of different indices for rating quality of cast aluminum alloys.

ADOPTION OF QUALITY INDICES WITH REFERENCE TO STUDIES OF MECHANICAL BEHAVIOR OF CAST ALUMINUM ALLOYS

Ammar et al.^[25] studied the effects of alloying elements, solution heat treatment time, and the quenching media on the mechanical properties and quality of 413-type alloys. They further prepared quality charts that enabled selection of chemical composition, solution heat treatment time, and the quenching medium to arrive at the best-performing alloy.

Sibal et al.^[26] successfully used the quality index Q_0 to determine the effect of process parameters like aging temperature and modification on the quality of the alloy 354. They also monitored the effect of interrupted heat treatments T6I4 and T6I6 on the quality of the material, using Q_0 as quality index.

Alexopolous and Pantelakis^[27] studied the dependency of hardness and tensile properties on the aging treatment of alloy A357 using quality maps.

Caceres^[17] presented a simple continuum mechanics model relating quality index to parameters of the deformation curve of alloys A356/357. The study explored the possibility of using quality index Q to optimize the combination of alloy chemical composition and temper.

Tiryakioglu et al.^[21] used the quality index Q_E to evaluate the structural integrity of cast AlSiMg alloys. They concluded that the index can be successfully applied regardless of processing history and chemical composition.

Alexopolous^[23,24] produced quality maps to aid the design engineer to select the appropriate material for a particular application based on the quality rating of the alloy. The quality maps allow for a systematic assessment of the effect of chemical composition, solidification rate, and heat treatment on the mechanical performance of the material. He reviewed usefulness of various quality indices and their strengths and weaknesses for carrying out quality rating.

The use of quality indices for cast aluminum alloys has been reviewed by Tiryakioglu et al.,^[22] where they look at the similarities and shortcomings of different quality indices. They also recommend the use of Q_T as it is applicable to all alloys and gives a realistic assessment of the quality of the cast alloy.

Based on the various studies cited in this section, it can be concluded that approach based on quality indices has been successful, with reference to selection of both the alloy and processing conditions for maximized performance.

EFFECT OF HIPPING ON THE MECHANICAL BEHAVIOR OF ALUMINUM ALLOYS

In the following, researchers dealing with Hipping of cast aluminum alloys and the benefits accruing in terms of mechanical behavior are briefly reviewed.

Nyahumwa et al. studied the effect of Hipping on the fatigue life of Al-7Si-Mg alloy.^[28] They reported that Hipping resulted in the significant improvement in fatigue life due to the deactivation of entrained double oxide film defects as fatigue crack initiators.

Lee et al.^[29] studied the failure mechanisms in A356 alloy under fatigue loading conditions. In non-Hipped material, porosity contributed to early nucleation and propagation of fatigue cracks. In contrast, in Hipped material, porosity was present to a much smaller extent and consequently had little or no influence on fatigue life. Fatigue cracks initiated at eutectic Si particles and propagated along them. Hipped material showed fatigue strength improvement of 40%–50% over the non-Hipped material.

The effect of Hipping on porosity in alloy A357 and stir-cast A357/15 vol% SiC particulate metal matrix composite was studied by Atkinson et al.^[30] and Zulfia et al.^[31] The studies brought out that Hipping leads to significantly reduced material porosity under optimum conditions.

Yi et al.^[5] carried out microstructure-based fatigue life prediction for A356-T6 alloy. Based on fractographic examination and finite element analysis simulation, they concluded that Hipping leads to significant reduction in porosity and consequently an improvement in the fatigue life of the alloy.^[5]

Ran et al.^[32] studied the effect of Hipping on the microstructure and tensile properties of unmodified A356-T6. Hipping significantly reduced porosity volume fraction and pore sizes, thereby improving ductility.

The study done by Rich et al.^[9] on cast aluminum alloys AMS 4220 and 4225 showed that Hipping led to improvements in ultimate tensile strength, ductility, and Charpy impact toughness for both the alloys. It was further observed that Hipping led to a significant increase in cycles to crack initiation for AMS 4225 alloy.

Gupta et al.^[33] studied the strain hardening behavior of Hipped and non-Hipped castings of aluminum alloy 354; they reported that Hipped components have higher hardening capacity and generally higher strain hardening rate compared to the non-Hipped ones.

Ceschini et al.^[34] studied the effect of Hipping on the fracture behavior of sand cast A356-T6 and A204-T6 alloys. Hipping significantly reduced solidification defects such as gas pores and shrinkage cavities. Hipping led to a reduction in fatigue data scattering and a ~40% increase in fatigue resistance.

Based on the various researches on the subject, it can be concluded that Hipping under optimum conditions improves the mechanical behavior of cast aluminum alloys under both monotonic and cyclic loading conditions.

EFFECT OF HIPPING ON DIFFERENT QUALITY INDICES FOR ALLOY 354

Studies on the effect of different quality indices were all carried out on cast aluminum alloy 354. In the following part of this contribution, the treatment is hence confined to this alloy. Effect of Hipping on the quality of the alloy was studied over a range of aging conditions. Details of manufacture of the material used for the studies are given in the following.

Melting

Alloy 354 was received in the form of 14-kg ingots. It was cleaned, dried, and melted continuously in a 500-kg capacity SiC crucible, using a thyristor-controlled electrical resistance furnace. The melting temperature was maintained at $740 \pm 5^\circ$. The casting process involved modification using strontium additions. Strontium was added as an Al-10% Sr alloy. Addition was done so as to control strontium in the castings in the range 70–105 ppm. Molten metal was degassed using pure, dry nitrogen injected into the melt for ~30 min by means of a rotating graphite degassing impeller, at a rotation speed of 600 rpm. Table 1 shows the mean chemical composition of the alloy used in this study. All the values are in weight percent. The chemical analysis was carried out using arc spark spectroscopy with an ARL spectrometer in the laboratory attached to the melting facility.

Casting

Compressor wheel castings were produced from the liquid metal. The molds used for the casting are made of special grade of plaster of Paris. The molds are dried in an electrical heating oven at 220° to remove moisture. Once the liquid metal is ready for pouring, casting is done using the dried molds using a counter gravity process.

Hipping

Hipping process consisted of holding the material for 6 h at $505 \pm 5^\circ$ in an inert nitrogen atmosphere at a constant pressure of 525 ± 5 bar.

Heat Treatment

Heat treatment consisted of solution treatment and aging. Solution treatment was carried out at $524 \pm 5^\circ$ for 6 h in the single α -phase field in an electrical thyristor-controlled forced air batch furnace. Quenching was done using water bath maintained at 60° – 80° . Material was then artificially aged, with natural aging (NA) proceeding in some instances.

Size and Dimensions

Hipping as well as heat treatment was carried out on compressor wheel castings. The size/dimensional details are shown in Fig. 3.

Aging Treatments Studied

In the work done by Dineshbabu et al.,^[35] the effect of Hipping was studied using two types of aging treatments. The first type comprised two steps, and the details are given in Table 2. The second type comprised different preceding NA times, and the details are given in Table 3. The aging treatments were carried out on both Hipped and non-Hipped materials to enable a comparison.

Artificial Aging in Two Steps

Table 2 shows the values of yield strength R_p (MPa), % elongation to fracture, strain energy density $\bar{W}$ (MJ/m³), and quality indices Q_0 , Q , and Q_c in units of MPa for Hipped and non-Hipped samples of alloy 354 after two different two-step aging treatments. In the first treatment, the samples were subjected to artificial aging at 100° for 2 h followed by artificial aging at 170° for 5 h. In the second treatment, the samples were subjected to artificial aging at 100° for 5 h followed by artificial aging at 170° for 5 h. It was noted

Table 1 Mean chemical composition of the alloy 354 (in Wt. Pct.)

Si	Cu	Fe	Mg	Mn	Zn	Ti	Ni	Pb	Cr	Sn	Al
9.0	1.69	0.08	0.53	0.04	0.003	0.16	0.04	0.001	0.002	0.002	Bal.

that all the yield strength values lie in a narrow range (295–300 MPa) and that %elongation to fracture values are higher for the Hipped castings. The values of W and quality indices Q_0 , Q , and Q_C were found to be higher for the Hipped condition of the alloy as compared to non-Hipped condition, and this was true for both first and second aging treatments. Thus, Hipping improved the quality rating of the alloy 354. Improvement in the quality of the alloy 354 after Hipping was brought out by all the three indices Q_0 , Q , and Q_C .

Fig. 3 Drawing of compressor wheel casting (dimensions in mm)

Different NA Times Preceding Artificial Aging

Table 3 shows the values of yield strength R_p (MPa), %elongation to fracture, strain energy density W (MJ/m³), and quality indices Q_0 , Q , and Q_C in units of MPa for Hipped and non-Hipped castings of alloy 354 with three different times of NA (0, 40, and 120 h) preceding artificial aging at 188° for 5 h. It was noted that %elongation to fracture values are the same or higher for Hipped castings as compared to non-Hipped ones, and this was true for all the three NA times. The values of W and quality indices Q_0 , Q , and Q_C were found to be higher for the Hipped condition of the alloy as compared to the non-Hipped condition, and this was true irrespective of the preceding NA time. Thus, Hipping improved the quality rating of the alloy 354. Improvement in the quality after Hipping was brought out by all the three indices Q_0 , Q , and Q_C .

CONCLUSIONS

1. Hipping results in an increase in the value of quality indices Q_0 , Q , and Q_C for castings of aluminum alloy 354 over a wide spectrum of aging treatments.
2. Hipping is also done for other cast aluminum alloys as an industrial practice. While calculations dealing with the effect of Hipping on quality indices are available only for alloy 354, Q_0 , Q , and Q_C are expected to serve as useful quality indices for monitoring improvements accruing from Hipping even for other cast aluminum alloys.

Early History of Aluminum Metallurgy

Norman C. Craig

Chemistry and Biochemistry, Oberlin College, 119 Woodland St, Oberlin, OH, 44074,
United States

Abstract

Prior to the mid-1880s aluminum was known as a metallic substance but was too costly to be used for other than jewelry-type applications. In 1886, Charles Hall in the United States and Paul Héroult in France discovered an economical electrolysis process for reducing aluminum from its abundant ore, alumina (Al_2O_3). This method, known today as the Hall–Héroult process, was a direct application of the then-new development of dynamos and principally of waterpower to generate huge amounts of electricity. Within a few years, aluminum was being produced at a low enough price that this metal played a growing role in everyday life. As a lustrous and lightweight metal, aluminum transformed human expectations for the appearance and uses of metals. This paper traces the stories of Hall and Héroult in their historic paths from concept to industrialization for refining aluminum metal. The essentials of the Hall–Héroult process remain fundamental in the aluminum industry today.

Keywords: Alumina (Al_2O_3); Charles M. Hall; Cryolite (Na_3AlF_6); Electrolysis; Electrothermy; Frank F. Jewett; Oberlin college; Paul L. T. Héroult; Reduction.

NAME FOR ALUMINUM

Today “aluminum” is so-called in the United States but not in most of the world. Elsewhere, this substance is called “aluminium.” In the mid-1880s, when the revolution occurred in the production of metallic aluminum, the common name in the United States was “aluminium.” Charles Hall used this name in his early writings and in his patent applications.

After working on various methods to extract aluminum from its compounds, Humphrey Davy declared in 1809 that he would have used the name “aluminum” for this new metal derived from “alum,” an aluminum sulfate. Other European scientists preferred the name “aluminium” because this metal was also derived from “alumina,” aluminum oxide. The “ium” ending had been agreed upon for naming new metals. Davy compromised on “aluminum.” In the third edition of his monograph (1896) on p. 6, *Aluminium*:..., J. W. Richards remarked “in recent years, some Americans have used this ‘aluminum’ spelling”.^[1] That version was applied in 1907 when the Pittsburgh Reduction Company (PRC) was renamed the Aluminum Company of America (Alcoa). Additional remarks on the growing use of “aluminum” in the 1890s in the United States may be found in Edwards, Frary, and Jeffries, *Aluminum and its Production*.^[2] They reported “when the metal became commercially available in America, popular usage very quickly omitted one syllable from its name, and it became ‘aluminum’ again.”

ELECTROTHERMY AND ELECTROLYSIS

To understand the electrical methods applied to the extraction of aluminum metal, recognizing the distinction between *electrothermy* and *electrolysis* is essential. In *electrothermy*, high electric currents are supplied to mixtures of reactants in well-insulated chambers to produce very high temperatures by resistive heating. Relative high voltages (10s of volts) are also needed. The intent is to get reactions to occur that depend on high temperatures. In the late 1800s, most chemists still believed that the secret to getting difficult reactions to occur was obtaining very high temperature. Electrothermy provided the means to achieve these temperatures with a reasonable expenditure of resources. The large currents needed for electrothermy became practical after the development of commercial electric dynamos in the late 1870s.

In contrast to electrothermy, for *electrolysis* the electric current (D.C.) acts as a supplementary chemical reagent at the two electrodes. The equivalent of a current (ion transport) passes through a liquid medium. In electrolysis, chemical reactions occur that would be impossible without an induced flow of electric current. Two parts of the reaction (anode reaction and cathode reaction) must be separated in space, thereby preventing a back reaction to form reactants again. The voltage in electrolysis is low (<10 V). Electrolysis does not require a high temperature. However, in electrolysis some resistive heating of the medium occurs unavoidably. The high temperature in the

Fig. 1 Inscribed 100-ounce aluminum pyramid atop the Washington Monument in Washington, DC. Detre Library and Archives, Sen. John Heinz History Center

process developed by Hall and Héroult was required to melt and to keep molten the cryolite solvent and was otherwise not needed. Use of electrolysis for chemistry traces back to Humphrey Davy's production of reactive metals at the beginning of the 1800s.^[3] The initial development of the electrolysis process for making aluminum metal was confounded by confusion about the distinction between *electrothermy* and *electrolysis*.

CHEMICAL REDUCTION OF ALUMINUM

By 1854, Henri Sainte-Claire Deville in France had developed a practical chemical method for reducing aluminum chloride to significant amounts of the metal. This difficult chemistry brought the price of aluminum down to that of silver metal. Thus, aluminum fell in the class of jewelry metals. A crowning example of the use of aluminum from its jewelry age occurred 1884. A partly hollow, inscribed pyramid of 100 ounces of aluminum metal was placed as an ornament and the tip of the lightning rod system on the top of the Washington Monument in Washington, DC (Fig. 1). Prior to its installation, the aluminum pyramid had been displayed in Tiffany's jewelry store in New York.^[4] William Frischmuth in Philadelphia refined the aluminum by the chemical process and cast the pyramid.

The chemical method for extracting aluminum metal consisted of the reaction of metallic sodium and sodium aluminum chloride. Sodium metal and aluminum chloride were both hard to handle because of reactivity with oxygen or water in the atmosphere. At the time, the industrial

preparation of sodium metal depended on reducing the sodium in sodium carbonate mixed with coke and oil at high temperature, where sodium metal distilled away from the reaction mixture. Aluminum chloride was prepared by passing chlorine gas over a mixture of aluminum oxide (alumina) and carbon at high temperature.^[5]

Prior to the success of Sainte-Clair Deville, in 1825, Hans Christian Oersted in Denmark had made poor quality aluminum metal by reducing aluminum chloride with a potassium amalgam (mercury solution) and distilling off the mercury.^[6,7] In 1827, Wöhler in Germany had made somewhat better aluminum metal by the reduction of aluminum chloride with pure potassium metal.^[8] He improved this process in 1845 by passing aluminum chloride vapor over potassium metal.^[9]

ALTERNATIVE TO CHEMICAL REDUCTION

The cost and difficulty of the chemical method for making aluminum metal led a number of chemists to seek alternative methods. A promising step was the electrochemical method tried independently by Sainte-Claire Deville and Robert Bunsen in the early 1850s.^[10] This method involved electrolysis of molten sodium aluminum chloride. However, battery-sourced electricity was too expensive, as was the synthesis of sodium aluminum chloride. In addition, the aluminum reduced from the melt was not easily harvested in its dispersed solid state or easily replaced in the melt. Useful electrolysis to make aluminum metal had to await the development of powerful electric dynamos after the late 1870s and new discoveries.

The successful competitors were two young men, Charles Martin Hall in the United States and Paul Louis Toussaint Héroult in France (Fig. 2). Both were born in 1863. The placement of the aluminum cap on the Washington Monument in 1884 was a strong incentive to Hall,

Charles M. Hall *P. Héroult*

Fig. 2 Charles M. Hall at age 21 in 1885 (left). Paul L. T. Héroult (right) in 1888. Oberlin College Archives and Institut pour l'Histoire de l'Aluminium, Paris

who succeeded with an electrochemical method within less than 2 more years. Héroult came to the same method by an independent path.

EDUCATION OF CHARLES HALL

At 12 years of age in Oberlin, OH in 1876, Charles Hall became interested in chemistry and specifically in the problem of aluminum metallurgy. He traced his start in chemistry to reading his minister father's college chemistry textbook. That book was Alonzo Gray's *Elements of Chemistry*, first published in 1840.^[11,12] The book contained little durable theory other than formulas for compounds. It emphasized descriptive properties and provided methods for doing practical chemistry. Hall nearly started a fire in the cupola of his family's home by trying some of the experiments. Hall quoted the essential material on aluminum from the Gray text in his acceptance speech for the Perkin Medal Award in 1911:^[13]

The metal may be obtained by heating the chloride of aluminum with potassium in a covered platinum or porcelain crucible and dissolving out the salt with water. As thus prepared it is a gray powder similar to platinum, but when rubbed in a mortar exhibits a distinctly metallic lustre. It fuses at a higher temperature than cast-iron and in this state is a conductor of electricity but a non-conductor when cold.

This description traces to the work of Friedrich Wöhler in 1827.^[14] Once Charles Hall became interested in aluminum, he encountered reports about Sainte-Clair Deville's famous book on aluminum, *De l'Aluminium, ses Propriétés, sa Fabrication et ses Applications*, in which Sainte-Clair Deville reported that "every clay bank was a mine of aluminum".^[15,16]

When Charles Hall entered Oberlin College in 1880, he went to Cabinet Hall to purchase some supplies for experiments from the brand new professor of chemistry and mineralogy, Frank Fanning Jewett (Fig. 3). Jewett at age 39 had just arrived from 4 years of teaching chemistry at the Imperial University in Tokyo, Japan. Prior to that time, Jewett had assisted Wolcott Gibbs at Harvard. He had spent a year (1873–1874) in Friedrich Wöhler's laboratory in Göttingen, Germany, where he acquired a sample of aluminum metal. He had two degrees from Yale. He was not only as well educated in chemistry as any academic in the United States, but also he was a world traveler. A younger and an older aluminum enthusiast met on the Oberlin College campus in Cabinet Hall in 1880 (Fig. 4).

In college, Hall took the one course in chemistry that was offered in his junior year. However, before that course, already self-educated in chemistry, Hall did numerous experiments in Jewett's college laboratory seeking improvements in conventional carbon-based reduction methods for aluminum metallurgy. After the course, he

Fig. 3 Professor Frank F. Jewett, ca 40 years old. Oberlin College Archives

Fig. 4 Cabinet Hall at Oberlin College, where Professor Frank F. Jewett taught chemistry and had his private laboratory. Oberlin College Archives

attempted electrolysis of aluminum salts in water. These experiments were unsuccessful. A full account of the technical path Hall followed is available in the *Journal of Chemical Education* with the title "Charles Martin Hall; the Young Man, His Mentor and His Metal".^[17] This paper was presented at the 1986 celebration of the centennial of the discoveries by Hall and Héroult at the New Orleans meeting of the Light Metals Section of the Metallurgical Society. Christian Bickert of Pechiney Corporation presented a companion talk about Héroult with the title "Paul Héroult – The Man behind the Invention".^[18]

Unnoticed in previous accounts of the history of aluminum were Charles Hall's insightful remarks in his commencement oration at Oberlin College in June 1885.^[19] His brief talk bore the title, "Science and the Imagination." The first sentences were "The imagination is the poetic faculty. It is also the faculty of the sciences." Hall had done enough research to understand that imagination was as essential to doing fruitful science as it was to writing good poetry, undoubtedly a surprising declaration to those in the commencement audience. Hall's search for a new method

to extract aluminum was a consequence of a deliberate research agenda.

ELECTROLYSIS METHOD FOR ALUMINUM IN THE UNITED STATES

Soon after Charles Hall received his B.A. in June 1885, he moved his explorations of aluminum metallurgy to his woodshed laboratory attached to his family home in Oberlin (Fig. 5). In October 1885 in the *Scientific American*, Hall read about Grätzel's success in making magnesium metal by electrolysis of molten magnesium chloride.^[20,21] To explore suitable molten salts as solvents for aluminum oxide, the abundant ore, Hall adapted to his oven a high-temperature burner fired by gasoline (Fig. 6). A bellows-driven, coal-fired oven was not hot enough. Tests of a number of fused fluorides led to success in dissolving

alumina in cryolite (sodium aluminum fluoride), which melted at 1000°C. This signal experiment was done on February 9, 1886 or earlier.^[22] Electrolysis of alumina dissolved in molten cryolite with graphite electrodes in a clay crucible failed. Bunsen-Grove cells to supply the current were homebuilt. Using a graphite crucible insert and some added aluminum fluoride,^[23] Hall succeeded in making some small shiny pellets by electrolysis on February 23, 1886. Jewett confirmed them as aluminum metal (Fig. 7). Liquid aluminum metal (melting point 660°C) was produced on the graphite crucible, which was the cathode (–), and carbon oxides were produced on the graphite rod that served as the anode (+). Only the aluminum from the oxide was reduced. The cryolite solvent, which also contained bound aluminum, was unaffected. For a continuous process, aluminum oxide could be periodically added to the melt and spent ends of carbon anodes replaced by lowering the anode rods into the melt. With a limited current supplied by batteries, external heating was needed to keep the reaction mixture molten. On February 23 and 24, 1886 Hall wrote two technically robust letters to his older brother George, who was a Congregational minister in Dover, NH. Charles asked his brother to save these postmarked letters.^[24] Hall was 22 years old.

In addition to Hall's remarkable energy and inventiveness, his work succeeded because of Jewett's expert knowledge and material support, which included supplying initial laboratory space and materials for the Bunsen-Grove cells (zinc/sulfuric acid/concentrated nitric acid/clay cups) that produced the high electric current needed.^[25] Contributing to Hall's success was his proximity to industrial Cleveland, where he could readily get gasoline for the furnace from Standard Oil, sulfuric and concentrated nitric acids for the batteries from Grasselli Chemical, and graphite rods for electrodes and for fashioning crucibles from Brush

Fig. 7 A cut-open graphite crucible from a reproduction of the original Hall experiment. Shiny circles in the bottom are halves of aluminum pellets. Author's photograph

Electric. Hall synthesized many of his chemicals, including pure cryolite, aluminum fluoride, and alumina. He also cast large zinc electrodes for Bunsen-Grove cells.^[26]

STEPS TO COMMERCIAL DEVELOPMENT

Charles Hall lacked the financial resources for commercial development of his electrolysis method for refining aluminum. In the late spring of 1886, his older brother George recruited two financial backers, Judge Henry Baldwin and his neighbor, Simeon Brown, located in Allston, MA near Boston. They supported the application for a patent that was filed on July 9, 1886 by the Washington law firm of Mason, Fenwick, and Lawrence. Soon, Hall learned of a patent interference due to the prior application for a U.S. patent on May 22, 1886 by Paul Héroult, who had received a French patent on April 23, 1886. If a U.S. inventor could prove that he had reduced his invention to practice before the date of the application by the foreigner, the American had a valid claim. In the patent interference testimony recorded in October 1887, the key evidence in Hall's favor consisted of the two, postmarked letters that he sent to his brother. U.S. Patent No. 400, 766 was issued to Hall on April 2, 1889 (Fig. 8).

With the financial support of Baldwin and Brown and assistance from young Dwight Baldwin, Hall worked to develop his process in Allston, MA until the middle of the fall of 1886. There he had a small dynamo to supply the needed current. At that time, the Boston backers withdrew their support because Hall had difficulty developing his method. The present author and a coworker, Lewis McCarty, confirmed that the small-scale process^[27] is troubled by irreproducibility.

HALL'S ARRANGEMENT WITH THE COWLES BROTHERS

Back in Oberlin, Hall worked through the winter and the first part of 1887 on his own with his original equipment until he secured an agreement with the Cowles brothers in late 1887 to support further explorations of the electrolysis process. The Cowles had a successful metal business, called the Cowles Electric Smelting and Aluminium Company in Cleveland and in Lockport, NY, where they made aluminum bronze (*ca* 10% aluminum with copper) by *electrothermy* of a mixture of alumina, graphite, and copper. Waterpower in Lockport generated the large electric currents needed for this high-temperature process.

Hall was assigned to Lockport to work on the development of his process. The Cowles brothers provided him minimal resources and technical support. Their primary interest was to control a possible competitor. Disappointed in Hall's progress, the Cowles brothers terminated the agreement with him in the middle of 1888. During the time

in Lockport and before, Hall explored a range of salts for altering solvent mixtures, different materials for anodes, and different cell designs with the goal of improving the reliability and efficiency of the method. These investigations led to four more patent applications, which have been evaluated in a paper with the title "Charles M. Hall's Persistent Quest of Patents for Refining Aluminum Metal by Electrolysis".^[28] These additional patents were awarded on April 2, 1889 along with the basic patent.

FORMATION OF THE PRC

When the Cowles brothers terminated the agreement with Hall, Romaine C. Cole, an employee of the Cowles brothers and a former employee of Alfred Hunt, a metallurgist in Pittsburgh, PA, saw potential in Hall's method. Cole forged a link between Hall and Hunt, which was supported by a prospectus about the electrolysis process and its industrial potential that Hall penned.^[29] In August 1888, Hunt had secured funding for the PRC. A pilot plant was set up on Smallman Street close to the large steel mills, where Hunt had started out. This plant was fitted with a

C. M. HALL.

PROCESS OF REDUCING ALUMINIUM BY ELECTROLYSIS.

No. 400,766.

Patented Apr. 2, 1889.

Fig. 8 Diagram from Hall's principal U.S. patent

Fig. 9 Electrolysis with external heating, first commercial-scale smelting at the Pittsburgh Reduction Company in November 1888. Detre Library and Archives, Sen. John Heinz History Center

large, steam-engine-powered Westinghouse dynamo to provide sufficient current for a major development of the electrolysis process.

At the outset, Hall constructed a scaled-up version of the external heating method (Fig. 9) he had first used in Oberlin. By Thanksgiving Day in late November 1888, Hall and his new assistant, Arthur Vining Davis, were making aluminum metal by electrolysis.

With scale-up, Hall found that the problems of the small-scale process largely disappeared. However, with *external heating* the reaction pots had short lifetimes, and the anodes were hard to adjust as they were consumed in the electrolysis process. By early 1889, Hall had switched to the method of *internal heating*, which he had described as a potential improvement in his prospectus. Additional current flow maintained the needed high temperature. Open steel pots lined with graphite were much more durable, anodes were easier to adjust than inside an oven, liquid aluminum was easier to remove from the bottom of the pots, and alumina readily added as needed

Fig. 10 Lithograph of pots with internal heating at the Pittsburgh Reduction Company on Smallman Street, ca 1890. Alcoa Inc

Fig. 11 Sketch of the Niagara Falls plant of the PRC, ca 1900, the first aluminum smelter in the United States to use water power to generate electricity. Detre Library and Archives, Sen. John Heinz History Center

(Fig. 10). Charles Hall played the central role in developing all of this new technology and thereby establishing methods that were a long-term basis for the aluminum industry. Alfred Hunt provided the business leadership.

EXPANSION OF THE PRC

As markets for inexpensive aluminum metal grew, the modest plant on Smallman Street was abandoned in 1892 in favor of a site in New Kensington on the Allegheny River north of Pittsburgh. Soon the cost of steam-powered generation of electricity was recognized as too great. A new plant using waterpower was opened in 1895 at Niagara Falls, NY (Fig. 11). Smelting at New Kensington ceased. Additional water-powered smelters in Quebec, Canada (Shawinigan Falls 1899) and elsewhere in western New York (Massena 1903) soon followed. Waterpower was confirmed as the prime source of electricity for smelting aluminum in the western hemisphere.

LEGAL BATTLES WITH THE COWLES BROTHERS

Two legal battles occurred between the PRC and the Cowles brothers. The first was initiated in 1891 when the PRC found that the Cowles Company was secretly making pure aluminum by the Hall process in Lockport, NY. Judge Howard Taft ruled in favor of the PRC in 1893. In 1897, the Cowles brothers brought suit against the PRC on the grounds that the Cowles possessed the Bradley patents needed for the method of *internal heating*, which was not described in the Hall patent. *Electrothermy*, which was the Cowles essential method, was entirely dependent on internal heating. The final legal decision in 1903 was a “tie”. The PRC could not use internal heating for electrolysis without paying for a license from the Cowles Company; the Cowles

Company could not make pure aluminum by the electrolysis process without a license from the PRC. By the early 1900s, the PRC had developed into a large industry. For the Cowles to catch up with the PRC was impractical; they settled for selling aluminum made by the PRC at a favored price.^[30] The chemist, writer of this article, views the legal judgment as technically flawed. One cannot do electrolysis without some internal heating. All that Hall had done was to increase the internal heating with some extra current. Of course, using internal heating depended on an abundant supply of current, which was unavailable to Hall in his initial experiments done with homemade batteries. In 1907, the name of PRC was changed to the Aluminum Corporation of America (Alcoa).

The True Story of Aluminum

In 1958 Alfred Cowles, a younger relative of the Cowles brothers, wrote a book, *The True Story of Aluminum*, with the goal of establishing the Cowles brothers as the inventors of the *electrolysis* process for refining aluminum.^[31] Much of the argument in this book turns on obscuring the difference between *electrothermy*, which the Cowles brothers used to make aluminum bronze, and *electrolysis*, which Hall used to make pure aluminum. This critique of *The True Story* was confirmed in a thorough analysis of this book written by Francis Frary, onetime Director of Research at Alcoa.^[32] Frary's 1958 evaluation came to light in 2015, when Edward S. Acton, the son of an early head of the plant at Shawinigan Falls, died. Frary wrote as follows:

The author is apparently either ignorant of certain fundamental facts in connection with the process he discusses, or else deliberately overlooks them in his argument. It seems worthwhile, therefore, to discuss some of his statements from a technical point of view, on the basis of my practical experience with both carbon-resistor furnaces of the Cowles type [electrothermy] and electrolytic cells [electrolysis] for the production of aluminum.

The fundamental fallacy in the argument of the book is that the Cowles brothers invented and patented the idea of producing heat inside of a furnace or a cell by passing an electric current through it.

JULIA HALL MYTH

During the last quarter of the twentieth century, a myth took root that Julia Hall, Charles Hall's next-older sister, had played a contributing role in the *technical* aspects of the discovery and the development of the electrolysis process. The seeds of this myth are in the made-up story line and the made-up conversations in Edwards' *The Immortal Woodshed* biography of Charles Hall.^[33] Martha Moore Trescott reinforced this myth with an article in the *Journal of Chemical Education*^[34] and a chapter about Julia Hall in *Dynamos and Virgins Revisited*.^[35] Trescott made faulty

use of archival materials to support her claim. A detailed refutation of the arguments advanced by Trescott, which depended on a careful reevaluation of the archival materials, showed that Julia Hall had no role of consequence in the technical aspects of the discovery and development of the electrolysis process.^[36]

ELECTROLYSIS METHOD FOR ALUMINUM IN FRANCE—PAUL HÉROULT

Fewer original documents exist regarding the technical discovery path followed by Paul Héroult in France than exist for Hall's work. However, the outlines of Héroult's life and work are well known. He was born in Normandy in 1863. During the Franco-Prussian War (1870–72) and beyond, young Héroult and his mother stayed for 3 years with his maternal grandfather in England,^[37] thereby giving Héroult a lifelong facility with the English language. Héroult became interested in entrepreneurial activity and in aluminum, in particular, as a youth. In 1875 Héroult's father moved his leather tannery business to Gentilly, a southern suburb of Paris.^[38] For his secondary education, Héroult attended the Sainte-Barbe Academy in Paris. During this time, Héroult read widely from books in the extensive library of a family friend, M. Belliot.^[39] Among the books he encountered was Deville's *De l'Aluminium*, which inspired Héroult's interest in pursuing new methods for aluminum metallurgy by electrical methods.^[40] Héroult was already skilled at drawing. A sketch in a notebook anticipates the electrochemical cell he later used (Fig. 12). After a year of

Fig. 12 Héroult's sketch of an electrolysis vessel from his notebook at the École de Mines. Institut pour l'Histoire de l'Aluminium, Paris

preparation and a fine performance on the entrance examination, Héroult enrolled at the École de Mines in Paris in 1882. His inspiration at the school was Professor Henri Le Chatelier, who was interested in aluminum metallurgy. Héroult was so distracted in devising plans for aluminum reduction that he did poorly on the examinations and was dismissed at the end of the first year. He spent 1883–1884 in military service.^[41]

EXPERIMENTS IN THE GENTILLY TANNERY

When his father died in 1885, Paul Héroult inherited the tannery in Gentilly and moved there to work fulltime on aluminum metallurgy. The tannery contained a steam engine and a small Gramme electric dynamo. Two friends from the École de Mines, Louis Merle and Lucien Van Kerquistel, joined Héroult in this work. Louis Merle's father, Henri Merle, had owned the chemical factory known as La compagnie des produits chimiques d'Alais et de la Camargue (PCAC) in Salindres in southern France. Metallic aluminum was obtained there by Sainte-Claire Deville's chemical process. In the first experiments at the tannery, Héroult used the small dynamo to attempt electrolysis of aluminum salts in water, but he met failure, as did Hall with this approach. For some of his exploratory experiments, Héroult reported using Bunsen-[Grove] "elements" as a source of electricity.^[42]

Believing he needed very high temperatures, Héroult sought a dynamo capable of producing large electric currents. His mother provided funds from constrained

family resources to make the substantial purchase. This new dynamo, a Bréguet (400 A–30 V),^[43] may have been the largest dynamo available. It made possible many experiments with large electric currents, an approach that was unavailable to Hall in Oberlin. Initial electrolysis experiments with molten cryolite were at high temperatures. The iron cathode crucible developed fissures from alloying with aluminum. With a graphite crucible as cathode, the small amounts of dispersed aluminum metal would not coalesce. Adding copper oxide solved the coalescence problem but degraded the purity of the aluminum. To lower the melting temperature of the bath, Héroult added sodium aluminum chloride. Upon noticing that the carbon anode was attacked, Héroult concluded that an oxide must be present to provide oxygen for the anode-consuming reaction. He then realized that the sodium aluminum chloride stock had been substantially hydrolyzed into alumina and that alumina dissolved in cryolite was being electrolyzed. Further successful experimentation involving alumina dissolved in molten cryolite led to his French patent No. 175,711 filed on April 23, 1886 (Fig. 13). The process depended on *external heating* in an oven. The same as Hall, Héroult was 22 years old.

HÉROULT SEEKS FINANCIAL BACKING

Accompanied by Louis Merle, Héroult took word of his new process to Alfred Rangod Pechiney at Salindres in 1886 (Fig. 14). When Henri Merle died in 1877, Pechiney succeeded him as director of PCAC. Héroult hoped to interest Pechiney in adopting the new process to make pure aluminum. Pechiney dismissed the commercial value of pure aluminum and pointed to the established value of aluminum bronze (copper-aluminum alloy). In a letter written later in 1891, Pechiney revealed that he "disliked" electricity.^[44] Ironically, Pechiney was later to gain control of the electrolysis-based aluminum industry in France, which became known as Pechiney Corporation.

ALUMINUM INDUSTRY IN EUROPE

Following his encounter with Pechiney, Héroult returned to Gentilly to resume work on electrolytic production of aluminum alloys. Positive results led to a brief supplementary patent filed on April 15, 1887,^[45] in which alumina in the presence of copper metal in a graphite crucible was reduced to aluminum bronze at a high temperature. Cryolite was not involved as a solvent. The patent also applied to making aluminum alloys with iron and silicon. Héroult claimed that “electrolysis” occurred in molten aluminum oxide. This claim seems quite doubtful. Aluminum oxide melts at 2054°C, a very high temperature. The ingredients of graphite, aluminum oxide, and copper were present for *electrothermy* in the manner of the Cowles process that occurred at a lower temperature without melting aluminum oxide. Furthermore, it is hard to imagine how Héroult could have observed that aluminum oxide had melted in the encased crucible. The patent gives no direct evidence of molten aluminum oxide. Further evidence in support of electrothermy rather than electrolysis comes from J. W. Richards’ calculation that the current was too low for electrolysis under the reported conditions of the industrial operation of Héroult’s process.^[46]

In the meantime, Héroult transferred his patents for making aluminum alloys to the Schweizerische Metallurgische Gesellschaft (SMG), soon renamed Aluminium Industrie Aktien Gesellschaft (AIAG) and located in Neuhausen, Switzerland at the Rhine Falls, where electricity was generated by waterpower. In the United States, the Cowles brothers had used water power by 1886 in Lockport, NY to make aluminum bronze.

At Neuhausen, the German metallurgist Martin Kiliani joined Héroult in developing the alloy process and then in the production of pure aluminum.^[47] Concerned about crust formation that interfered with resupplying alumina to the cells, Kiliani introduced movement of the anode carbon (rotation and up and down). He also lowered the temperature of the pots by adding aluminum fluoride,^[47] as Hall had also done in his original experiments. By 1890 pure aluminum was being produced at Neuhausen.

Meanwhile, Héroult had moved to Froges near Grenoble, France in 1889 to become the technical director of the new Société Électro-Métallurgique Française (SEMF) that produced pure aluminum. Key developments were the introduction of large, fixed carbon anodes and rotation of the pots to counteract crust formation (Fig. 15). Ultimately, rotation of the pots was found unnecessary, and square pots were introduced. The large carbon anodes and pot liners were fabricated at a plant near Froges under the guidance of Léon Hulin, whose association with Héroult traced to Gentilly.^[48] A larger water-powered smelter was built at La Praz in the Maurienne Valley of Alpine France in 1893. The consequence of a number of steps of development, the aluminum industry was now fully launched in Europe. The close association of water power with the

smelting of pure aluminum in Europe anticipated by more than five years the same development by the PRC in the United States.

A full account of Héroult’s work in developing pot technology may be found in Maurice Laparra’s paper, *The Aluminum False Twins*.^[49] Laparra also carries the PRC/Alcoa story further than has been done in the present account. Marco Bertilorenzi traces the Héroult patents in detail.^[50] George David Smith supplied a full account of the PRC/Alcoa story in *From Monopoly to Competition*.^[51] Hall’s involvement in technical developments at PRC/Alcoa is understated in *The Aluminum False Twins*. In the early days, Hall was the principal figure in developing new methods and had several patents for doing so. Hall did not detour into making aluminum bronze. He had developed successful pot technology for smelting by 1889. In subsequent years, details of the smelting technologies that developed in the United States and in Europe converged. Despite prodigious research, the fundamental method for smelting aluminum remains the same as in the invention of Hall and Héroult.

HALL AND HÉROULT MEET

Although Paul Héroult had made prior trips to the United States, the first recorded meeting with Charles Hall occurred in New York 1911. That was when Hall received the prestigious Perkin Medal as a joint presentation of the Society for Chemical Industry, the American Chemical Society, and the American Electrochemical Society (Fig. 16). Héroult gave a light-hearted address following Hall’s account of the path to his discovery of the electrolysis process. Héroult concluded with:^[52]

My friend Hall and myself have been fighting for fifteen years, most of the shots going wild on account of

Fig. 15 Rotatable pots or “marmites” initially developed by Paul Héroult for the plant in Froges. Institut pour l’Histoire de l’Aluminium, Paris

the long range over the Atlantic Ocean. Since we met, however, we conceived a better opinion of each other, and I take great pleasure in extending to my friend Hall my sincere congratulations on the award to him of the Perkin Medal.

In the summer of 1912, Hall and Héroult met again. The Héroult family was vacationing on an island in Lake Placid in New York. Hall's nephew, George W. Hall, who was 16 years old, rowed his uncle, by then a partial invalid, out to visit the Héroults. Elisabeth, Héroult's youngest daughter, who was then 9 years old, recalled the visit.^[53,54] On the way back to shore in the rowboat, a severe thunderstorm struck. The boat was almost swamped, and the Halls were drenched. Nonetheless, they made it back safely. Neither Hall nor Héroult was to live beyond 1914, their 51st year. On the centennial of their discoveries (1986), they were celebrated together at the meeting of The Metallurgical Society in New Orleans, the American city where French and American heritages combine. By this time the electrolysis method for smelting aluminum had truly become the Hall–Héroult Process.

Fig. 17 Aluminum high-voltage power lines being inspected. James L. Amos, National Geographic Creative

ALUMINUM METAL IS KEY TO LONG-DISTANCE POWER TRANSMISSION

Long-distance electric power transmission is the most important use of aluminum metal. This application transcends the many uses in aircraft, other transportation, building materials, and the food industry. Without long-distance power transmission the electric grid that modern society depends upon would not be possible. The power lines little noticed high above the ground are fabricated with many strands of wire made from an aluminum alloy wrapped around a steel interior, which provides added strength (Fig. 17). This technology was developed at PRC/Alcoa in the early years of the twentieth century. In sum, electricity is essential for extracting aluminum metal from its ore; then aluminum enables the electric grid on which modern life depends.

ALUMINUM TRANSFORMS EXPECTATIONS FOR EVERYDAY METALS

The availability of inexpensive aluminum transformed societal expectations for the properties of everyday metals. In a speech at Oberlin College for the 50th anniversary of the discovery of the Hall–Héroult process, Edward R. Weidlein, then president of the American Chemical Society, made this case.^[55] Prior to 1886, metals were of two types: shiny precious metals such as gold, platinum, and silver, which were too expensive for use other than for jewelry and special decoration; dull ordinary metals, such as iron and copper, that were subject to “rusting” unless regularly polished or protected with coatings. Aluminum itself was lastingly bright and shiny. It was suitable for ornamentation as well as structures. An outstanding early example of the use of aluminum for ornamentation was the 1906 Postsparkasse (postal savings bank) in Vienna, Austria designed by the famous architect, Otto Wagner. A later example of note is Severance Hall (1931) in Cleveland, OH where the Cleveland Symphony Orchestra performs. The attractiveness of aluminum led to the development of other durable, bright metals, which include chromium plate and stainless steels for use in everyday life. Aluminum has truly brightened up our world.

ACKNOWLEDGMENTS

The author is deeply in debt to Emily Acton Phillips, the great grandniece of Charles Hall. As the active family historian, she supplied several essential leads to unnoticed archival materials. Maurice Laparra, as President of the Institute for the History of Aluminum in Paris, played a crucial role in helping the author access important publications and documents related to Héroult's work. Emily Phillips and Maurice Laparra are, in effect, coauthors of

this account but bear no responsibility for any opinions or slips of the pen. The author is also indebted to Kenneth Grossi, the archivist at Oberlin College, to Mary Jones, the librarian at the Sen. John Heinz History Center in Pittsburgh, and to Nathalie Postic, iconographer at the Institut pour l'Histoire de l'Aluminium in Paris.

Homogeneous Modifier-Treated AlSi₁₀Mg Alloy: Microstructure and Mechanical Properties

Tomasz Lipiński

Faculty of Technical Sciences, University of Warmia and Mazury in Olsztyn,
Oczapowskiego 11, Olsztyn, 10-719, Poland

Abstract

The microstructure of an unmodified hypoeutectic Al–Si alloy comprises large primary alpha phase and eutectic alpha phase dendrites and eutectic beta phase crystals. The mechanical properties of silumins can be improved through chemical modification. This article discusses the modification of an EN AC- $\text{AlSi}_{10}\text{Mg}$ hypoeutectic alloy with the use of a modifier made of processed alloys and an Al–Si alloy solidified at the velocity of 373, 473, 573, and 673 K/s. The applied alloys were referred to as homogeneous modifiers. The content of modifiers in the silumin alloy reached 0.3%–1.5% by weight. The alloy was subjected to tensile strength, relative elongation, and hardness tests before and after modification. The alloy was cast into a sand mold. The results of the study indicate that alloy microstructure can be modified and its mechanical properties can be improved by incorporating the proposed homogeneous modifiers into a liquid alloy. Mechanical properties were improved when an Al–Si modifier with higher silicon content than the modified alloy was used and when the cooling rate was increased to 573 K/s. A further increase in the cooling rate of the modifier did not lead to a significant improvement in the mechanical properties.

Keywords: Al–Si alloys; Homogenous modifier; Mechanical properties; Modification; Modifier; Silumin.

INTRODUCTION

In industrial practice, hypoeutectic and hypereutectic alloys are mainly used. The microstructure of a hypoeutectic Al–Si alloy comprises large primary alpha phase and eutectic alpha phase dendrites as well as eutectic beta phase crystals, whereas hypereutectic silumins have a large primary beta phase and eutectic microstructure. This microstructure is responsible for the low mechanical strength of silumins.^[1,2] Hypereutectic silumins are used mainly in the production of engine pistons.^[3] Hypoeutectic and near-eutectic silumins are significantly more common in industrial practice.

The mechanical properties of silumins can be improved by modifying the temperature gradient,^[4,5] technological processes,^[5,6] heat processing parameters,^[7,8] and treatments with chemical elements and compounds.^[9–11] Modifications involving chemical mixtures are most widely applied in industrial practice. Despite numerous attempts to improve chemical treatments,^[12–15] alloys are often modified with chemical elements, which, when the alloy is recycled, can exert a negative influence on the repeated modification process when a modifier with a different chemical composition is used. The process of modifying silumin microstructure was described by Pacz in 1921.^[16] The eutectic growth process was described by Jackson

and Hunt.^[17] The generalized Jackson–Hunt model has been updated several times.^[18–20] The formula proposed by Wołczyński^[20] contains the most general definition of eutectic growth. The above laws have been positively verified, but they are used only in laboratory tests and computer simulations of eutectic growth. Silumins have also been modified in exothermic reactions.^[21–23] In this approach, the effectiveness of modification is reinforced by an exothermic reaction that disrupts the crystallization process.

When the influence of an exothermic mixture on the modification process was compared with the effect exerted by individual mixture components, researchers found that process effectiveness could be improved by modifying the proportions of the introduced elements and compounds and altering the composition of the modifier to maximize its energy efficiency. The exothermic effect alone was capable of modifying a silumin. Exothermic reactions involve highly complex phenomena, including the collision theory, reaction energy, and movement of fluids and mixture components, and their influence on the alloy. The parameters describing changes in fluids as a function of temperature and time are unknown, which poses a considerable problem. Exothermic processes should induce temperature differences in microregions. Microregions with a lower temperature (higher cooling), which result from

the application of modifiers that are reaction products, can use the energy released by the reaction for nucleation, thus minimizing the degree of cooling required for crystallization. This behavior can be explained by disruptions in the stability of the dendritic front. The crystallization front is deformed and ceases to be flat. The exothermic peak does not grow in a stable manner, and it undergoes bifurcation. The above is accompanied by the formation and growth of secondary dendrites whose stability also deteriorates. The process is repeated multiple times until the entire area of the crystallization front is filled. Silumin treatment with an exothermic modifier exerts a significant influence on the microstructure and performance of alloys. Unfortunately, exothermic modification is a technologically complex process.^[23,24]

A method for treating Al–Si alloys with a homogeneous modifier was proposed to improve alloy performance, minimize its environmental impacts, and eliminate chemical elements that could exert a negative effect on alloy parameters after recycling.^[25–30] Hypoeutectic and near-eutectic silumins require different modification than hypereutectic alloys. The proposed modification method was tested on a hypoeutectic silumin, due to the popularity of the former group.

Al–Si ALLOY TREATED WITH A HOMOGENEOUS MODIFIER

The experiment was performed on an EN AC- AlSi₁₀Mg hypoeutectic alloy,^[31] produced industrially, and supplied in the form of pig sows. The chemical composition of the raw analyzed alloy is presented in Table 1.

The alloy was melted in an Al₂O₃ crucible in an electric furnace and modified at a temperature of 1023 K (AlSi₁₀Mg) for 5 min. Upon the completion of each modification stage, specimens were collected for metallographic and mechanical tests. Cylindrical samples, 8 mm in diameter and 75 mm in length, were poured into a sand casting mold. Hardness was determined by the Brinell method. The lateral surface of the specimen head was ground to a depth of 2 mm in a static tensile test. Three measurements were taken per sample (six measurements per cast). The tensile stress test was performed on a specimen with a 5:1 length-to-diameter ratio in a universal tensile tester. Ultimate tensile strength and percentage elongation were determined. All measurements were carried out according to standard ISO 4498:2010,^[32] with a standard steel ball, 2.5 mm in diameter, under a load of 612.9 N, in the

HPO 250 hardness tester. A tensile strength test was performed on two samples, $\phi = 6$ mm, for each melting point, according to standard ISO 6892-1:2016.^[33]

The mechanical properties of the AlSi₁₀Mg raw alloy cast in a sand mold obtained in this experiment are presented in Table 2. The microstructure of the basic AlSi₁₀Mg alloy is presented in Fig. 1.

A homogeneous modifier was prepared from the alloy that would subsequently undergo treatment. The modifier and the treated alloy had the same chemical composition. The AlSi₁₀Mg alloy was melted in a crucible with Al₂O₃ at a temperature of 750°C. The melted alloy was heated for 10 min. The liquid alloy was solidified at the velocities of $V_1 = 373$, $V_2 = 473$, $V_3 = 573$, and $V_4 = 673$ K/s. Alloys were ground mechanically and passed through sieves to obtain a fraction with a particle size of 0.32–0.40 mm. The modifier was crystallized on a copper liquid-cooled disk. A thin layer of silumin was poured on the disk. Cooling conditions and disk rotation were selected experimentally to obtain the desired cooling speed. Modifiers with different cooling rates were obtained for each alloy. They were incorporated into liquid silumins at 0.3%, 0.6%, 0.9%, 1.2%, and 1.5% of alloy weight. Modified silumins were cast in sand molds. Solidified silumins were broken out of molds and subjected to mechanical strength tests.

The microstructures of the AlSi₁₀Mg alloy treated with various homogeneous modifiers are presented in Figs. 2–6.

An analysis of the microstructure of the original alloy and alloys treated with a homogeneous modifier revealed changes in the size of eutectic components ($\alpha + \beta$). The non-processed alloy contained thick β phase lamellae and grains surrounded by α phase microstructures (Fig. 1). A minor modification effect was achieved after treatment with 0.3% and 0.6% modifier (wt%) cooled at $V_1 = 373$ K/s

Table 2 Mechanical properties of the raw AlSi₁₀Mg alloy

Alloy	Mechanical properties		
	Tensile strength, R_m (MPa)	Elongation, A (%)	Brinell hardness, HB
AlSi ₁₀ Mg	142	0.6	54

Fig. 1 Microstructure of basic AlSi₁₀Mg alloy, etched with Mi8Al, magnification 200×

Table 1 Chemical composition of the raw AlSi₁₀Mg alloy

Alloy	Chemical composition (wt%)									
	Si	Cu	Mg	Mn	Fe	Ti	Ni	Zn	Pb	Al
AlSi ₁₀ Mg	9.3	0.03	0.35	0.28	0.30	0.10	0.02	0.02	0.02	Ball

Fig. 2 Microstructure of the alloy modified with 0.6% $\text{AlSi}_{10}\text{Mg}$ cooled at $V_1 = 373$ K/s, etched with Mi8Al , magnification $200\times$

Fig. 5 Microstructure of the alloy modified with 0.9% $\text{AlSi}_{10}\text{Mg}$ cooled at $V_3 = 573$ K/s, etched with Mi8Al , magnification $200\times$

Fig. 3 Microstructure of the alloy modified with 1.5% $\text{AlSi}_{10}\text{Mg}$ cooled at $V_1 = 373$ K/s, etched with Mi8Al , magnification $200\times$

Fig. 6 Microstructure of the alloy modified with 1.5% $\text{AlSi}_{10}\text{Mg}$ cooled at $V_3 = 573$ K/s, etched with Mi8Al , magnification $200\times$

Fig. 4 Microstructure of the alloy modified with 0.6% $\text{AlSi}_{10}\text{Mg}$ cooled at $V_2 = 473$ K/s, etched with Mi8Al , magnification $200\times$

(Fig. 2). When the content of the modifier was increased from 0.6% to 1.5%, finer and more organized β phase microstructures were observed in the alloy (Fig. 3). At a cooling rate of $V_2 = 473$ K/s, modifying effects were observed when the modifier content ranged from 0.6% to 1.5% (Fig. 4). At cooling rates of $V_3 = 573$ and $V_4 = 673$ K/s, similar microstructural changes were observed in the processed alloys. A fine eutectic microstructure ($\alpha + \beta$) was observed already with a modifier content of 0.3%, and it increased with a rise in modifier content to 0.9% (wt%) (Fig. 5). A further

increase in the modifier content did not induce significant changes in the microstructure (Fig. 6).

An analysis of β phase distribution in visibly modified alloys revealed that β phase lamellae were separated by a similar distance. In view of the Jackson-Hunt model, this observation could point to the stability of crystallization.

The tensile strength of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content and modifier cooling rate with regression equation and coefficient of determination is presented in Figs. 7–10.

The relative elongation of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content and modifier cooling rate with regression equation and coefficient of determination is presented in Figs. 11–14.

The Brinell hardness of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content and modifier cooling rate with regression equation and coefficient of determination is presented in Figs. 15–18.

An analysis of changes in the mechanical properties of the $\text{AlSi}_{10}\text{Mg}$ alloy treated with a homogeneous modifier revealed a correlation between the compared properties and the microstructure for identical modifier parameters and identical modifier content. For modifiers with cooling rates of $V_1 = 373$ and $V_2 = 473$ K/s, the analyzed mechanical properties improved with an increase in modifier content

Fig. 7 The tensile strength of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 373 K/s

Fig. 11 The relative elongation of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 373 K/s

Fig. 8 The tensile strength of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 473 K/s

Fig. 12 The relative elongation of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 473 K/s

Fig. 9 The tensile strength of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 573 K/s

Fig. 13 The relative elongation of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 573 K/s

Fig. 10 The tensile strength of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 673 K/s

Fig. 14 The relative elongation of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 673 K/s

Fig. 15 The Brinell hardness of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 373 K/s

Fig. 16 The Brinell hardness of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 473 K/s

Fig. 17 The Brinell hardness of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 573 K/s

across the entire range of values. For modifiers with cooling rates of $V_3 = 573$ and $V_4 = 673$ K/s, mechanical properties improved with a decrease in the modifier content and were stabilized when the modifier content reached around 0.9% of silumin weight. High tensile strength, high relative elongation, and high hardness values were noted for alloys with 1.2%–1.5%, 0.9%–1.5%, and 0.9%–1.5% modifier content (wt%) and cooling rates of 473, 573, and 673 K/s, respectively. The above results indicate that homogeneous modifiers cooled at different rates can produce alloys with similar mechanical properties. The results for modifiers cooled at 573 and 673 K/s are similar, which suggests that similarities can also be expected at higher cooling rates.

Fig. 18 The Brinell hardness of the $\text{AlSi}_{10}\text{Mg}$ alloy with different modifier content for modifier cooling rate 673 K/s

Fig. 19 The tensile strength of the $\text{AlSi}_{10}\text{Mg}$ alloy with 1.0% modifier made from the Al–Si alloy with a cooling rate of $V_3 = 573$ K/s

The observed changes in the mechanical properties of silumins can be attributed to their fine and organized eutectic microstructure. The modification produced silicon lamellae with rounded tips, which points to the effectiveness of the analyzed homogeneous modifier. Sharp edges increase the risk of microcracking (notches). Oval tips increase the alloy's tensile strength and relative elongation.

THE INFLUENCE OF SILICON IN A HOMOGENEOUS MODIFIER ON THE MECHANICAL PROPERTIES OF THE $\text{AlSi}_{10}\text{Mg}$ ALLOY

The results of $\text{AlSi}_{10}\text{Mg}$ alloy treatment with a homogeneous modifier made from a processed alloy were similar to the changes induced by a modifier made with Al and Si components. The tensile strength of the $\text{AlSi}_{10}\text{Mg}$ alloy treated with 1.0% modifier made from the Al–Si alloy with a cooling rate of $V_3 = 573$ K/s is presented in Fig. 19, and the relative elongation achieved with a homogeneous modifier (made identically) is presented in Fig. 20.

At a constant modifier cooling rate, the highest tensile strength and relative elongation were noted in alloys with approximately 15% Si content, i.e., when their silicon content was higher than the silicon content of the processed alloy. The above could be attributed to the fact that more silicon can be incorporated into a eutectic silumin with an

Fig. 20 The relative elongation of the AlSi₁₀Mg alloy with 1.0% modifier made from the Al–Si alloy with a cooling rate of $V_3 = 573$ K/s

increase in its crystallization rate (coupled zone). Tensile strength and relative elongation were lower than in alloys treated with a modifier made from the processed alloy. The above could indicate that the remaining alloy components also influence the modifier's effects.

CONCLUSIONS

The following conclusions can be drawn from the results of this study:

1. Silumins can be effectively treated with homogeneous modifiers.
2. The microstructure and mechanical properties of alloys are influenced by the cooling rate and the content of a homogeneous modifier.
3. A modifier composed of the main alloy components (Al and Si) can be effectively used to treat alloys.
4. The mechanical properties of the AlSi₁₀Mg alloy treated with a homogeneous modifier were somewhat inferior to those reported in alloys modified with chemical mixtures. Nonetheless, the analyzed method does not lead to the degradation of an alloy's chemical composition when highly effective chemical modifiers are introduced in small quantities. The environmental impacts of the analyzed method are thus minimized.

Honeycomb Composite Structures of Aluminum: Aerospace Applications

D. L. Majid, Nor Hafizah Manan, and Yee Ling Chok

Department of Aerospace Engineering, Faculty of Engineering, Universiti Putra Malaysia, Serdang, Selangor, 43400, Malaysia

Abstract

A honeycomb composite structure is usually composed of a lightweight hexagonal core sandwiched between two thin face sheets that are adhesively joined. Both the core and the face sheets can be combinations of many types of materials depending on the application. In this article, an overview of the design and manufacturing process of aluminum honeycomb composite structures particularly for aerospace application is presented. Aluminum honeycomb composite structures are lightweight constructions with high specific strength and stiffness that are applied mainly in the aerospace industry. An aluminum honeycomb panel is typically made up of the secondary structural components and interiors of an aircraft such as the wing skin, trailing edge, control surface, flooring, partitions, aircraft galleys, and overhead bins, to name a few. Other applications are in the spacecraft, helicopter, missile, and satellite. Owing to its honeycomb design peculiar to the hexagonal beehives, it can reach more than 30 times higher in stiffness and 10 times higher in flexural strength compared to its solid counterpart of the same weight. The mechanical properties of the honeycomb composite structure hinge on the materials of the core and face sheets, the core geometries, and the thickness of the face sheets. Designed for superior flexural and shear loading, the selection of the optimal honeycomb design will depend on the application requirements. The principal design criterion of a sandwich structure in aerospace applications is weight saving, and there is a trade-off between performance and cost. In terms of manufacturing of the honeycomb composite sandwich structure, the two main processes are the expansion process commonly used for low-density cores and the corrugation process for higher density cores.

Keywords: Aircraft; Cell configuration; Corrugation; Expansion; Lightweight structures; Sandwich panel; Specific stiffness; Specific strength.

INTRODUCTION

Sandwich panels with lightweight cores deliver superior flexural, shear, and compression strengths at a minimum weight. Due to their superior flexural stiffness-to-weight ratio, sandwich structures result in lower lateral deformations, higher buckling resistance, and higher natural frequencies compared to their monolithic counterparts. For this reason, these structural shapes form an integral part of aerospace and spacecraft design. The lightweight cores used in aerospace applications are generally categorized into three main types: honeycomb cores, foam or solid cores, and corrugated cores. Foam or solid cores are generally inexpensive and comprise balsa wood and a wide selection of polymeric foam materials having varying densities and modulus. Examples of foam cores are polyurethane, polyisocyanurate, phenolic foam, and polystyrene.^[1] Honeycomb cores are usually made by expanding flat sheets of material lined with adhesive strips. In the case of corrugated cores, corrugated sheets are used instead.

The suitable combination of core and skin in a sandwich panel is governed by the mechanical and cost requirements. As an example, Nomex honeycomb cores with woven glass fiber skins are more resilient than panels with aluminum core but at great expense. If they are combined with woven carbon fiber skins, then the cost will increase further, but they are beneficial in terms of weight and stiffness.^[2] The sandwich core densities for airframe constructions are typically within 1.6–23 lb/ft³. Figure 1 shows several examples of aluminum and composite honeycomb sandwich panels.

Honeycomb, referred to as a hexagonal sheet structure, was first introduced as paper honeycomb by the Chinese around 2000 years ago. The first patent on manufacturing honeycomb was developed by Budwig in 1904.^[3] Honeycomb was made by aligning two paper bands at intervals together with the adhesive material arranged in parallel strips. This started the revolutionary development of sandwich composite structures that are primarily designed for efficient loading. The idea of using a honeycomb structure

Fig. 1 (a) Composite honeycomb core; (b) aluminum honeycomb sandwich panel

for aircraft construction really took off when a German aircraft designer, Hugo Junkers, patented an application of the first honeycomb core in aircraft in 1915. He proposed to replace the fabric covering on aircraft with metal sheets that can support compression if the sheet is connected at very small intervals with a series of square or rectangular cells or triangular or hexagonal hollow bodies. The problem of bonding a continuous skin to a cellular core structure however had led him to opt for an open corrugated structure, which could be riveted or welded together. In the same year, he successfully implemented the corrugated metal on the first all-metal airplane, the J-1 Blechesel, and later the F-13 all-metal transport in 1919 employing duralumin, a high strength aluminum alloy.^[4]

In the same year, Capt. Sundstedt, a Swedish pilot, designed and built a huge seaplane, named Sunrise that was lighter than other seaplanes, using balsa wood in the construction of the pontoons of which strength is of secondary importance. The two pontoons weighed only 400 pounds each even though they were 32 ft long and were capable of bearing a weight of 14 tons.^[5] The first aircraft panel was composed of thin mahogany facings bonded to an end-grain balsa wood core, employed by the Germans in 1919.^[6] The Italians had widely adapted plywood skins

glued to balsa wood as core in the primary structures of their seaplanes between World Wars I and II. The main obstacle at that point was the insufficient development of the adhesive that can bond the skins to the honeycomb directly due to the adhesive flowing down the cell walls.^[6]

In 1938, Norman de Bruyne, founder of a UK-based company called Aero Research Limited, further obtained a patent for manufacturing honeycomb, which is basically a shear web between two skins. He pioneered the applications in aircraft adhesives and impregnated fabrics and successfully achieved structural adhesive bonding of honeycomb sandwich structures. The company's significant contribution includes the Aerolite and Redux (metal-to-wood and metal-to-metal) adhesives, epoxy resin Araldite, Aeroweb Honeycomb cores, and Fibrelam panels.^[7] Redux was used in aircraft by the de Havilland aircraft company. Fibrelam is a Nomex (phenolic resin-dipped polyamide) honeycomb core with fiberglass facings.

The De Havilland Mosquito, a twin-engine, two-seater wooden plane, was designed in 1938. It used a balsa wood sandwich structure in the construction of the fuselage.^[8] It has a stressed skin construction also utilizing a sandwich panel of laminated plywood over balsa wood core. It was reported to be the first aircraft that used structural adhesive bonding for wooden frames of the aircraft; while the strength of the aircraft was found to be adequate, the moisture resistance was poor.^[9] However, it was proven to be a successful plane during World War II with superior speed.^[10]

Vinson^[11] reported that during World War II, the concept of sandwich construction in the United States originated with the faces made of reinforced plastic and a low-density core. As an example, in 1943, the Wright-Patterson Air Force Base designed and fabricated the Vultee BT-15 fuselage using fiberglass-reinforced polyester as the face material bonded to both a glass fabric honeycomb and a balsa core.

In the late 1940s, a band of fraternity brothers from the University of California, Berkeley formed Hexcel after their stint in the Navy together during World War II.^[7] Hexcel was in the front line at that time when strong lightweight materials are required. Its first military contract awarded by the Air Material Command at the Wright-Patterson Air Force Base was to develop honeycomb for radomes on military aircraft using fiberglass honeycomb. Until today, Hexcel plays an important role in the growth of sandwich structures and supplies more than 50% of the world's honeycomb core materials.^[11] In 1949, Hexcel's predecessor, California Reinforced Plastics, submitted an intentionally low bid to produce fuel cell support panels for the B-36 Peacemaker bomber. It marked the start of the company's involvement with the defense industry. A significant improvement in the bonding of the skins was achieved when epoxy resin was later introduced in 1954. Honeycomb cores then are mostly perforated at the cell walls due to outgassing of volatile adhesives when used

at a temperature higher than 100°C. Advances in modern nonvolatile adhesives permit the honeycomb design without perforation.

The successful implementation of honeycomb cores as structural panels were also notable in the B-58, B-70, and F-111 series, as well as in the production of helicopter rotor blades and also in Apollo spacecraft.^[12] The Convair B-58 Hustler was noted as the first United States bomber with supersonic dash capability. The supersonic dash of Mach 2.0 is preceded by a subsonic cruise of several 1000 miles and followed by a post-dash cruise segment. For light, strong, and stiff structures, the B-58 used aluminum honeycomb panels extensively at the outer covering of the aircraft.^[13] The sandwich panels were composed of aluminum skin with an aluminum or fiberglass honeycomb core. The smooth surface of the exterior was certainly a bonus. In spite of the remarkable impression that it made, the B-58's run was only for a period of less than 10 years, and one of the causes was the corrosion of aluminum honeycomb due to trapped moisture that seeped through the bonded joints.

The B-70 Valkyrie was designed for a cruise speed of Mach 3 and an operating altitude of 70,000 ft. At this speed, the air rushing past the airframe heats it up and can rise up to 330°C at the nose and leading edge parts. To withstand these extreme temperatures, brazed stainless steel and titanium honeycomb panels are used. The development of this aircraft, however, never proceeds beyond the experimental/prototype stage.^[14]

The Lockheed C-5 military transport airplane is one of the largest aircraft in the world and the largest airlifters in its inventory during the 1960s. It contained more than 1,000 bonded honeycomb panels, which totaled over 35,000 per cubic foot.

A summary of some of the historical development of honeycomb panels as explained in the text is presented in Table 1. The 1970s were the start of the extensive application of composite materials in aerospace applications including

the honeycomb structures. Since then, the honeycomb composite structures have evolved tremendously, and today they have contributed to many useful applications.

The applications of aluminum honeycomb structures in the aerospace sectors today include both structural and secondary components of aircraft, helicopter, missile, spacecraft, and satellite. Some of the examples of aircraft components made up of aluminum honeycomb structures are aircraft heating, ventilation and air conditioning systems, wing skin panels, wing trailing edges, flooring, partitions, aircraft galleys, overhead bins, bulkheads, interior panels, and control surfaces. In the case of an aircraft with stressed skin design, the wing skins often use honeycomb sandwich panels. Honeycomb core in the aircraft can be constant thickness or tapered as shown in Fig. 2.^[15] Tapered core honeycomb panels are frequently used as flight control surfaces and wing trailing edges. Distribution of honeycomb core in a large jet aircraft is shown in Fig. 3.^[15] In the case of the Space Shuttle, the use of aluminum alloy and titanium honeycomb panels is due to the high strength and high-temperature requirements. For example, in a helicopter the rotor blade structures are composed of a aluminum honeycomb structure on metal blades and a Nomex honeycomb on composite blades.^[16] The growth in various aircraft and space industries provides one of the key factors that drive the honeycomb sandwich material market. Aerospace industry is in need of materials with specific characteristics such as superior mechanical properties and low weight. Employing a honeycomb structure will lead to a reduction in overall weight of the aircraft and contribute to lower fuel consumption. A 50% growth over 2016's core material demand is expected by 2021 in the commercial aircraft sector.^[17] The increase in demand is propelled by the growth of lighter aircraft such as Boeing 787 and Airbus A350.

Honeycomb composite structures can be all-metal combinations or all-composite materials for greater strength and lighter construction. Composite materials are the perfect choice but at great expense, for example, Nomex

Table 1 Summary of the historical development of honeycomb panels

Year	Aircraft make	Issue
1919	Sunrise aircraft	Pontoons constructed from honeycomb composite
1938	De Havilland DH.91 Albatross	Plywood skin and balsa core sandwich
1938	De Havilland DH.98 Mosquito bomber	Bonded wood sandwich structure for wing panel Sandwich spruce veneer on balsa core with solid spruce core attachment for fuselage
1943	Vultee BT-15	Fuselage using fiberglass-reinforced polyester with glass fabric honeycomb and balsa core
1949	B-36 Peacemaker	First application of fiberglass honeycomb (Hexcel) on fuel support panels
1960	Convair B-58 Hustler	Most of the outer coverings (90% of wing and 80% of airframe) consisted of aluminium honeycomb with aluminum skins. Problems were in ascertaining and maintaining the integrity of the bonded joints
1964	B-70 Valkyrie	Titanium and brazed stainless steel "honeycomb" materials to withstand heating during sustained high Mach number portions of the flight
1968	Lockheed C-5	Used more than 1,000 bonded honeycomb panels, which are approximately about 35,000 ft ² of bonded sandwich materials

Fig. 3 Honeycomb wing construction on a large jet transport aircraft^[15]

honeycomb core with carbon fiber skins. Aluminum core with aluminum skin is preferred for medium strength and stiffness at low cost. To seek lighter construction, aluminum core can be combined with glass fiber skins at no additional cost. Even with technological advances in the composite material honeycomb technology, aluminum honeycomb will still remain a major contributor to the overall aircraft structures. Compared to other metallic honeycombs such as titanium, stainless steel, and Inconel, aluminum honeycomb is considered to be relatively inexpensive to produce.

ALUMINUM ALLOYS

A discussion on aluminum honeycomb would not be complete without an introduction to the material itself. Aluminum alloys replaced wood as the main airframe material in the early 1920s. Up to the 1990s, aluminum alloys dominated the airframe applications over other materials such as composites, titanium alloys, and steel. They are considered one of the key materials in an aircraft construction due to their high strength- and stiffness-to-weight ratio, good corrosion resistance and nontoxicity, high thermal

and electrical conductivity, nonmagnetic property, reflective appearance, and easy to manufacture. Aluminum is second only to iron in terms of abundance and is relatively low in terms of manufacturing cost. It is used primarily in packaging (cans, foils), architectural and structural applications, transportation (aircraft and space, land transportation, marine), electrical applications (electrical conductors), consumer durables (appliances and utensils, furniture), and portable tools.^[18] In commercial aircraft, the structural weights of aluminum in Boeing 747 and 777 are 81% and 70%, respectively. In the 1970s, the composites used in aerospace applications took off and continued to increase with increasing need for lighter and yet stronger aerospace materials. However, aluminum still remains the classic material of choice for aircraft construction, and the improved version of aluminum alloys with enhanced capabilities that are possible through advances in processing technology seeks to enhance their continued importance. This improved version can be rapidly used due to lower manufacturing and/or life cycle costs, low substitution risk, and use of existing material production infrastructure.^[19] Examples of improvement in the yield strength and specific stiffness of aluminum alloys are shown in Fig. 4.

Fig. 4 (a) Yield strength and (b) specific stiffness of Al alloys as a function of year of introduction^[19]

Characteristics of Aluminum and Its Alloy

The primary advantage of aluminum and its alloy is the specific weight, about 2.7 g/cc, significantly lesser than that of other metals. Pure aluminum usually is not usually intended for structural applications because it possesses lower strength and stiffness. The mechanical properties of pure aluminum, however, can be improved by addition of alloying elements. Common alloying elements are silicon, copper, magnesium, lithium, nickel, titanium, and zinc. Besides improving the strength and hardness, these alloying elements are also useful for reducing weight, increasing corrosion resistance, and improving manufacturing characteristics.

Aluminum and its alloy are available in the form of wrought or cast products. Wrought aluminum alloys can be further classified according to the hardening process: cold working or heat treatment. Heat-treatable aluminum alloys are hardened by a process called precipitation hardening. In this technique, small precipitates that are formed when the solid solubility limit of one alloying element in another is exceeded are uniformly dispersed within the matrix of the soluble phase. The precipitates increased the resistance to dislocation, which further improved the overall strength. Another hardening technique is through cold

working process such as mechanical reduction, sometimes in combination with annealing process.

Wrought aluminum alloys are designated by a four-digit number and usually followed by a temper designation. The first digit represents the major alloying elements. The second digit indicates the modification to the alloy, and the third and last digits represent other alloying elements. Table 2 highlights the main contribution of the major elements in the wrought aluminum alloy series. The categories of tempers are as follows: *F* (fabricated), *O* (annealed), *H* (strain hardened by cold working), *T* (heat treated), and *W* (solution treated).^[18]

Aluminum Alloy in Aerospace

The 2xxx and 7xxx series are the primary aluminum alloys applied in airframe structural components. The aluminum–copper alloys (2xxx) are used in damage tolerance applications such as the lower wing skins and the fuselage structure. Damage tolerance encompasses both high fracture toughness and low rates of fatigue crack propagation, particularly in the natural environment under loading spectra containing the occasional high tensile load.^[20] The 2024-T3 alloy has been one of the most widely used alloys in fuselage construction. It possesses moderate yield

Table 2 Wrought aluminum alloy series^[18]

Series	Major alloying element	Features
1xxx	Pure aluminum	Excellent corrosion resistance High electrical and thermal conductivity Good workability Low strength Not heat treatable
2xxx	Copper	High strength-to-weight ratio Low resistance to corrosion Heat treatable
3xxx	Manganese	Good workability Moderate strength Generally not heat treatable
4xxx	Silicon	Low melting point Forms an oxide film of a dark gray to charcoal color Generally not heat treatable
5xxx	Magnesium	Good corrosion resistance Good weldability Moderate to high strength Not heat treatable
6xxx	Magnesium and silicon	Medium strength Good formability, machinability, weldability Good corrosion resistance Heat treatable
7xxx	Zinc	Moderate to very high strength Heat treatable
8xxx	Other element	Good strength, electrical conductivity, formability, and ductility High corrosion resistance High stiffness

Hall–Petch–Hypoeutectic
Al–Fe

strength, good resistance to fatigue crack growth, and good fracture toughness. In the case of fuselage skin material, the strength of the material is less important compared to the ability of the skin to withstand cracks. The aluminum–zinc-based (7xxx) alloys are used mainly in higher strength applications such as the upper wing skins, as well as the internal ribs, frames, and landing gear. The high level of stresses applied on the upper wing skin creates a need for high compressive strength. Aluminum 2xxx alloys are slightly better in terms of high-temperature capability compared to 7xxx alloys.

Aluminum–lithium (Al–Li) alloys represent an advanced class of aluminum alloys offering up to 10% density reduction and 15% increase in stiffness, coupled with improvements in damage tolerance specifically in

resistance to fatigue cracks.^[20] Research efforts on the development of Al–Li alloys are ongoing, focusing on producing a balanced alloy in terms of strength, corrosion resistance, and toughness properties for a cost-effective aircraft material. Advances in the processing of aluminum also permit the tailoring of the improved version of aluminum alloys. For example, the powder metallurgy and rapid solidification techniques offer a wider range of chemical composition and rapid processing options that enable the development of new alloys with more wide-ranging capabilities.^[16] Examples of common aluminum alloys used for various aircraft parts are described in Table 3, and a comparison of aluminum alloys with other materials in terms of strength and stiffness is shown in Fig. 5.^[21] The biggest disadvantage of aluminum alloys in the aerospace industry

Table 3 Some Common Aluminum Alloys in Aerospace Sector

Series	Composition (%)	Features	Applications
2024	Al 90.7%–94.7%, Cu 3.8%–4.9%, Mg 1.2%–1.8%, Mn 0.3%–0.9%, Si 0%–0.5%, Fe 0%–0.5%, Zn 0%–0.25%, Zr 0%–0.2%, Ti 0%–0.15%, Cr 0%–0.1%, Other 0%–0.15%	• High strength • Excellent fatigue resistance	• Shear webs and ribs • Fuselage and wing skin • Engine cowls • Aircraft fittings
5052	Al 95.7%–97.7%, Cu Max 0.1%, Mg 2.2%–2.8%, Mn Max 0.1%, Si Max 0.25%, Fe Max 0.4%, Zn Max 0.1%, Cr 0.15%–0.35%, Other 0%–0.15%	• High-strength non-heat-treatable alloy • Medium to high fatigue strength • Good resistance to corrosion • Good weldability and formability	• Honeycomb sandwich core for wing panels • Helicopter blade
5056	Al 93%–95.4%, Cu 0%–0.1%, Mg 4.5%–5.6%, Mn 0.05%–0.2%, Si 0%–0.3%, Fe 0%–0.4%, Zn 0%–0.1%, Cr 0.05%–0.2%, Other 0%–0.15%	• High strength • Excellent formability • Excellent corrosion	• Aircraft floor • Aircraft leading and trailing edges • Missile wings • Fan casings • Fuselage components • Helicopter rotor blades • **as honeycomb core^[6]
6061	Al 95.8%–98.6%, Cu 0.15%–0.4%, Mg 0.8%–1.2%, Mn Max 0.15%, Si 0.4%–0.8%, Fe Max 0.7%, Zn Max 0.25%, Ti Max 0.15%, Cr 0.04%–0.35%, Other 0%–0.15%	• Good corrosion resistance and finishing ability • Moderate strength	• Aircraft landing mats • Wing and fuselage structures
6013	Al 94.8%–97.8%, Cu 0.6%–1.1%, Mg 0.8%–1.2%, Mn 0.2%–0.8%, Si 0.6%–1%, Fe 0%–0.5%, Zn 0%–0.25%, Ti 0%–0.1%, Cr 0%–0.1%, Other 0%–0.15%	• Medium strength • Improved corrosion resistance and formability • Virtually immune to exfoliation and stress corrosion cracking	• Fuselage panels • Leading and trailing edges • Engine cowlings
7075	Al 87.1%–91.4%, Cu 1.2%–2%, Mg 2.1%–2.9%, Mn Max 0.3%, Si Max 0.4%, Fe Max 0.5%, Zn 5.1%–6.1%, Ti Max 0.2%, Cr 0.18%–0.28%, Other 0%–0.15%	• Strength is similar to that of many types of steel • Good machinability and fatigue strength properties	• Al clad skin sheet • Structural plate components
7050	Al 87.3%–90.3%, Cu 2%–2.6%, Mg 1.9%–2.6%, Mn Max 0.1%, Si Max 0.12%, Fe Max 0.15%, Zn 5.7%–6.7%, Zr 0.08%–0.15%, Ti Max 0.06%, Cr Max 0.04%, Other 0%–0.15%	• Best combination of strength, stress corrosion cracking resistance, and toughness	• Fuselage frames • Bulkheads • Wing skins

Fig. 5 Comparison of strength and stiffness of different honeycomb core materials^[21]

is that the majority of them are susceptible to corrosion by atmospheric moisture in varying degrees. The moisture tends to leak into the innermost core structure and corrodes it. The implication for this corrosion will be the major cost of repair or replacement. Secondary surface treatment processes are usually required for applications in the aerospace sector. Typical aluminum alloys that are normally used for honeycomb in increasing order of strength are as follows:

1. 3003-H19, the lowest strength of the group, usually used for non-aircraft applications
2. 5052-H39, the most often used aircraft grade, available with a corrosion-resistant surface treatment
3. 5056-H39, the strongest of the regular aircraft grades, available with a corrosion-resistant surface treatment
4. 2024-T3 or T81, the most heat-resistant alloy and slightly stronger in some properties than 5056-H39, available with a corrosion-resistant surface treatment

Guidance on the design information on the mechanical properties of aluminum alloys for aerospace vehicle structures can be obtained from MIL-HDBK-5J.^[22]

HONEYCOMB COMPOSITE CONSTITUENTS

A sandwich honeycomb construction is best described as a low-density thick honeycomb core sandwiched between two thin face sheets as depicted in Fig. 6. From the figure, it can be seen that the sandwich honeycomb structure is comprised of (1) a pair of thin face sheets, (2) a thick lightweight core to separate the two face sheets and also to carry loads from one face sheet to another, and (3) adhesives that can function as shear and axial loads transmitted to and from the core. The honeycomb core and face sheets are manufactured from thin foil material, and the face sheets are composed of thin sheets of metallic or composite material. The honeycomb core can come as perforated foil in order to prevent isolated voids in the core.

Fig. 6 A honeycomb construction

Aluminum series of 2024, 5052, and 5056 foil cores are typically used in aerospace and naval applications. In the following sections, the honeycomb composite constituents comprising face sheets, honeycomb cores, and adhesives are presented.

Core Configuration

A basic core configuration is a cell unit illustrated in Fig. 7.^[23] The core is helpful in distributing loads and stresses on the face sheets. This attribute had made the cored sandwich an excellent design for absorbing the impact stresses. The compressive strength of a core helps in halting buckling failure from the face sheets. At the same time, the core's shear modulus prevents the skin from sliding independent of each other when bending loads are applied. The following list is the common terminology that we need to be familiar with when dealing with a honeycomb structure^[6] corresponding to a cell unit and honeycomb structure shown in Fig. 7:

1. Cell represents a single honeycomb unit, and the cell size is indicated by the distance of two parallel sides of the cell.
2. Ribbon is the flat sheet constituting the honeycomb, also called the web, parallel to L direction.
3. Node is the bonded portion of the adjacent ribbon sheets, whose length is denoted as d .
4. Free wall is the cell wall section free of bonding.
5. L direction is the core ribbon direction.
6. W direction is perpendicular to the ribbon direction.
7. T direction is the core direction parallel to the cell openings.

Fig. 7 Basic cell terminology^[23]

8. HOBE is a term used to express honeycomb before expansion.
9. CUE stands for core unexpanded, which is the solid block of bonded sheets.

There are four basic cell configurations: hexagonal, circular, triangular, and square shapes. Figure 8 illustrates the four basic cell configurations. Variations on these shapes can be found in the form of underexpanded, overexpanded (OX), and reinforced. Other possible variants are illustrated in Fig. 9.^[24]

Hexagonal Core

The hexagonal core is the most basic and common honeycomb configuration. A hexagon is widely known as one of the most efficient shapes to be found in nature. This is due to the strong structural support offered by the geometry. In order to increase the mechanical properties of this type of core, a reinforcement layer along the nodes in the ribbon direction can be added into the structural build. This is generally termed as reinforced hexagonal configuration. The hexagonal core is made available in both expanded and corrugated forms.

OX-Core

If the hexagonal core is expanded in the width (W) direction, it is termed as overexpanded. In this manner, the cell configuration leans toward a rectangular cell, which facilitates curving or forming in the " L " direction with reduced anticlastic curvature and without buckling the cell walls. The OX process increases W shear properties and decreases L shear properties compared to a hexagonal honeycomb.

Flex-Core

This type of configuration is the trademark of Hexcel Corporation (San Francisco, California) and follows the OX configuration. With its exceptional formability, this configuration offers higher shear strength than that of a comparable hexagonal core of equivalent density when dealing with curvatures of highly tight radii. Flex-core can be produced from a variety of materials that make a hexagonal honeycomb. Another form of Flex-core is made available and is referred to as Double-Flex™. This form of core is a large-cell Flex-core that is also superior in formability (similar to standard Flex-core) and possesses high compression properties.

Tube Core

Also a trademark of Hexcel Corporation, this configuration possesses a unique designed energy absorption system when a thin-walled column or a small diameter cylinder

Fig. 8 (a) Hexagonal, (b) circular, (c) triangular, and (d) square honeycombs

Fig. 9 Variants of the hexagonal honeycomb core^[24]

is required. Tube core configuration removes the crush strength loss that occurs at unsupported edges of conventional honeycomb. Tube core is formed with the alternate flat aluminum foil wrapped around a mandrel and adhesively bonded. The tube outside diameter can range from 1/2 to 30 in. and the lengths vary from 1/2 to 52 in.

Triangular and Square Cores

Triangular and square cores are among the common configuration to be applied in sandwich structures. From Fig. 8, it can be seen that the angle of the typical triangular honeycomb core is 60°. Studies were conducted to compare

the compressive strengths of the two configurations. It is found that the compressive strength of a square honeycomb is higher than that of a triangular configuration.^[25]

A honeycomb core is specified according to the material, cell characteristics, and density.^[26] The specification requirements of aluminum core for the aerospace sector are defined by SAE-AMS-C-7438, “Core Material, Aluminum, for Sandwich Construction”.^[27] According to the standard, the designation of the honeycomb core is defined by material, cell size, aluminum alloy type, foil thickness, and density. An example is Hexcel CRIII-1/4-5052-.002N-4.3 whereby CRIII® is an Al5052 honeycomb with corrosion resistance coating, having a cell size of 1/4 in., a non-perforated cell wall size of 0.002 in., and a density of the honeycomb of 4.3 lb/cc.^[28]

According to the standard, there are two grades of aluminum alloy acceptable for core material. Grade B core material shall be either alloy 5052 or alloy 5056 foil, whereas Grade C shall be alloy 2024-T3 or alloy 2024-T81. Grade B alloys possess superior strength. Table 4 presents some of the available forms and manufacturers that comply with this standard.^[28–30] Cell size normally ranges from 1/16 to 3/8 in., but cell sizes of 1/8 and 3/16 in. are most frequently used in aerospace applications. This range of cell size is considered a small cell size associated with higher density and higher strength. Honeycomb with larger cell sizes is mainly used for non-aerospace-related and less demanding applications. The following list comprises the important strength properties to quantify honeycomb:

- 1. Compressive strength (both bare and stabilized with facings).
- 2. Compressive modulus (stabilized with facings).
- 3. Crush strength (crucial to be applied in energy-absorbing applications).
- 4. Shear strength and shear modulus in both *L* and *W* directions.

Face Sheet

The primary function of the face sheets is to provide the required strength and stiffness to resist the axial, bending, and in-plane shear loadings. In order for the face sheets to perform accordingly and to be able to transfer loads to and from the core, the adhesive must provide a rigid bonding. Apart from carrying the major loads, face sheet material selection is also based on surface requirements, such as smoothness, wear resistance, and corrosion resistance. These face sheets sometimes have auxiliary functions, for instance, to provide a profile of proper aerodynamic smoothness, a rough nonskid surface, or a tough wear-resistant floor covering.^[31] According to the American Society for Testing and Materials (ASTM) B209 (Aluminum and Aluminum-Alloy Sheet and Plate), sheet can be defined as a rolled product with a thickness of at least 0.006 in. (anything thinner is called foil) and less than 0.25 in., although in structural applications, the thinnest nominal sheet thickness of much practical use is 0.024 in. (0.6 mm).

In structural sandwiches, the face sheets are normally of the same thickness and these are called symmetric sandwich structures. However, there are some cases in which the thickness of the face sheets pair is varied due to different loading conditions or working environments. These are generally termed a asymmetric sandwich structures.

Aluminum alloy and composite face sheets are generally preferred due to weight considerations. As stated previously, the face sheet thickness can be as low as 0.25 up to 40 mm depending on the design requirements. Typically, stronger aluminum alloys are considered for the face sheets compared to the core, such as 7075-T6 and 2024-T3 or 2014-T6. A variety of finishes are available for aluminum. Cost, appearance, and durability are the factors to be considered in selecting the type of finish to be applied to the aluminum sheet. Common finishes include mill finish (bare aluminum), anodizing, painting, and

Table 4 Some manufacturers’ listing of aluminum honeycomb panel

Manufacturer	Alloy type	Cell size (fraction of in.)	Cell configuration	Nominal density (pcf)
Hexcel ^[11]	Aerospace grade 5052 H39 (available with corrosion-resistant coating)	1/16, 1/8, 5/32, 3/16, 1/4, 3/8	Hexagonal core, Flex-core, OX, and underexpanded core	1.0–12.4
	Aerospace grade 5056 H39 (available with corrosion-resistant coating)	1/16, 1/8, 5/32, 3/16, 1/4, 3/8	Hexagonal core, Flex-core	1.0–9.2

The Gill Corporation ^[13]	DURA-CORE II 5052	1/8, 5/32, 3/16, 1/4, 3/8, 3/4	Hexagonal core	0.8–12.0
	DURA-CORE II 5056	1/8, 5/32, 3/16, 1/4, 3/8,	Hexagonal core	1.0–12.0

mechanical finishes. Some of the considerations in their use are discussed as follows:^[32]

1. Mill finishes
 - Aluminum tends to develop extremely thin, tough, invisible oxide coating on its surface immediately on exposure to air. This thin film is extremely fine and narrow on first forming but almost completely impermeable and can effectively resist attack by atmospheric corrosion. However, the aluminum sheet can be coated when certain appearance is desired.
2. Anodized finishes
 - Anodizing is the process where the formation of oxide coating on the surface of aluminum is accelerated to produce a thicker oxide layer than the naturally occurred formation. Being part of the metal, the anodized coating has excellent durability and is highly abrasion resistant.
3. Painted finishes
 - Coatings based on polyvinylidene fluoride resins have become the standard for architectural applications or painted aluminum. Generally, painting reduces minimum strengths from those of the bare product because the paint is baked on at temperatures that tend to anneal the aluminum.
4. Mechanical finishes
 - Mechanical methods, such as abrasion blasting and buffing, may enhance the appearance of aluminum without coatings. These methods are used to reduce the reflectance in an economical way, rather than waiting for natural weathering to occur.

Adhesive

The term adhesive refers to the substance used for the bonding of the honeycomb core sheets at the nodes and also for the attachment of the open cellular core structure to the stiff thin face sheets. Adhesive bonding is an alternative method of joining structures other than using mechanical fasteners. The method eliminates the added weight of using fasteners and therefore reduces the cost. In addition, adhesive bonded joints eliminate gaps, bulges, and protruding fasteners that produce drag on aircraft surfaces. In sandwich structures, its primary roles are to assemble the core and the skin into an integral structural part and provide the rigidity, stiffening, and stabilization of the core. The adhesive must rigidly attach the skins to the core material in order for loads to be transmitted from one skin to the other and to permit the structure to fulfill all the structural requirements. It should be able to withstand the applied forces so that separation of the skin and the core does not occur. Adhesive is also responsible for reinforcing core wall after crushing.^[31] The adhesives selected for sandwich structures are usually high in strength and stiffness because they are also required to carry substantial loads. In many instances, failures at core

are expected rather than cohesive failures. The adhesives are selected based on the strength, temperature compatibility, and the ability to form a fillet at the cell wall or some other way. This is needed to form a good bond with the minimal surface area of the end of some of the core materials. The fillet possesses good toughness and also strength. Besides, the adhesives are preferred when both the melt viscosity and the surface tension are high enough. These two properties aid in the adherence of adhesives in the fillet area and prevent the rundown of adhesives to the flat portion of the part and puddle.

There are many types of adhesives: some are strong and rigid, and others are weak and flexible. The latter are usually in the form of cement type, whereas those used for high-strength applications are mostly available in the form of liquids, pastes, or dry or supported films. Compared to thermoplastic adhesive options, thermoset adhesives are stronger and stiffer and commonly considered for high-strength applications. On the other hand, a high-strength adhesive will impart extra rigidity that is not needed for applications that may not necessarily require high strength. Careful selection base on the strength requirements is important. Another critical requirement for the adhesive is the peel strength, which is the force required to de-bond the joint parts. It is important to note that peel strength changes with time and temperature. As a general rule, a low peel strength or relatively brittle adhesive should never be used with very light sandwich structures which may be subjected to abuse or damage in storage, handling, or service. Other key considerations in selecting adhesives are service temperature requirements, acoustical absorption, moisture/humidity, heat transfer, and outgassing requirements.^[33] Particularly, in sandwich structures, the requirements for the bonding between the core and the face sheets are provided in MIL-A-25463.

There are some basic differences pertaining to the requirements for the bonding of the core to facings and the bonding of core sheets at nodes. These specific requirements are listed as follows:

- Fillet forming

In order to achieve a good attachment to an open cell core, such as honeycomb, the adhesive must have a unique combination of surface wetting and controlled flow during early stages of cure. This controlled flow prevents the adhesive from flowing down the cell wall and leaves a low-strength top skin attachment and an overweight bottom skin attachment. Typical fillets are shown in Fig. 10.

Fig. 10 Typical fillet forming

- Bond line control

It is the capability of the adhesive to resist being squeezed out from between faying surfaces when excessive pressure is applied to a local area of the part during cure.

- Toughness

In the case of sandwich core-to-skin bonds, toughness refers to the resistance shown by the adhesive toward loads which act to separate the facings from the core under either static or dynamic conditions. It has been found from experience that greater toughness in the bond line usually equates to greater durability and thus to longer service life.

MIL-HDBK-337 specified the adhesives for the metal-to-metal and also metal-to-core bonding according

to their strength, toughness, environmental durability, and processing characteristics. The adhesives are classified according to the range of curing temperatures as detailed out in Table 5. Elevated temperature cure adhesives are usually used for core-to-skin bonding. There are generally two types of adhesives:^[31]

1. Adhesive films with a substrate base such as nylon, woven glass, or polyester.
2. Foam adhesives are unsupported and are mainly epoxy type with fillers dispersed in them for processability.

Two of the most commonly applied adhesive systems used for sandwich construction are phenolic and epoxy

Table 5 Categorization of adhesives

Material	Type	Maximum service temperature	Cure temperature	Manufacturer's designation	Manufacturer	Remarks

resin. Phenolic resin is specifically for metal-to-metal bonding and it can withstand high temperature and has low dielectric properties.^[31] Phenolic resin is further classified according to the modifications as neoprene elastomer or butadiene-acrylonitrile synthetic rubbers or polyvinyls to enhance certain characteristics desired in the adhesive. For example, neoprene elastomer-phenolic adhesives can be applied as smooth films and display limited flow during the bonding process, neoprene phenol adhesives possess moderate shear strength at room temperature conditions, and nitrile elastomer-phenolic adhesives are designed for elevated temperature applications.

Modified epoxy adhesives existed in a variety of types such as epoxy nylon, epoxy polyamide, and phenolic epoxy.^[31,34] Epoxies modified with nylon or polyamide polymers are known to provide excellent fitting and controlled flow properties, with high strength and toughness, albeit they can be somewhat moisture sensitive. Some versions are available as two-sided tape adhesives, in which one side can be a rubber or vinyl-phenolic, and this version provides both excellent peel resistance and durability at the skin side and excellent peel resistance at the core side. Nitrile-modified epoxies are a broader group of materials that exhibit flow and toughness properties shown by the nylon epoxies, along with the durability and weather resistance of the vinyl phenolics. The phenolic epoxy emits water during curing and is used only when high strength, high durability, or high-temperature mechanical properties are desired.

Epoxy-based adhesives can exist in three forms: liquid, paste, and film adhesives. Liquid and paste adhesives are the two-part resin system of an epoxy and are frequently used to repair damaged aircraft assemblies, whereas film adhesives are used as structural adhesives in aerospace applications. Film materials are frequently supported by scrim cloth that serves to improve the handling of the films prior to cure, control adhesive flow during bonding, assist in bond line thickness control, and provide galvanic insulation. Epoxy had been reported to form good fillets and bonds between facings and honeycomb for sandwich construction.^[35]

In addition to the adhesive itself, adhesive primers are used to provide corrosion protection within the bond line, to promote adhesion between the adhesive film and the metal, and to protect the clean surface and provide longer time to assemble a honeycomb part. Commonly used adhesive primers are one-component, low-viscosity epoxy with strontium chromate.^[31]

HONEYCOMB DESIGN CONSIDERATIONS

The selection of honeycomb design will depend on the design criteria and requirements that are specified for an application. In aerospace applications, the main reason for utilizing a sandwich honeycomb composite structure

is weight saving that can be achieved without compromising the structural requirements. In addition, the sandwich structure eliminates, if not completely, the need for fasteners, which means smoother skin surfaces. For example, an airfoil with thin skin and stringers will deform and cause unwanted drag on the surface due to deformation of the thin skin and spacings between stringers. A honeycomb airfoil, on the other hand, will produce smooth air-flow over the skin instead. Fatigue resistance can also be improved due to the elimination of stress concentrations from rivet and bolt holes. For this reason, the structural design criteria will be further elaborated in this article. Prior to that, a discussion on the design requirements in general is provided.

Design Requirements

Depending on the applications, there are numerous design criteria that dictate the requirements for sandwich construction. MIL-HDBK-5, for instance, is one of the documents that provide guidance on the design information on the strength properties of metallic materials and elements for aerospace vehicle structures.^[22] In aerospace applications, sandwich honeycomb has been mainly driven by the need for lighter structures, and this leads to material options that are dominated by composite materials. Nomex honeycomb with carbon fiber face sheets is one example having extremely high specific strength and stiffness. But with more advanced materials, the production cost increases with the need for advanced tooling and processes. These relationships between weight saving, structural requirements, and cost are illustrated in Fig. 11. Trade-off and optimization analysis are usually conducted to maximize weight-saving and structural properties with constraints in cost. The relationship of these three criteria is interrelated where when one criterion changes, it will affect the other.

For example, consider a wing skin construction. If weight is the main design criterion, then a sufficiently thick wing skin that can sustain high loads and will not buckle is not the choice solution. A thin skin with stringers will work, provided the spacings between stringers are not too large which will cause the thin skin to buckle.

Fig. 11 Main design criteria

A honeycomb sandwich structure construction can be a solution to the buckling problem except in cases where the loads are low; then skin/stringer combination can be more economical. The strength characteristics of an aluminum honeycomb sandwich panel are dictated by the mechanical properties of the chosen alloy and the geometric properties for both facing and core. As an example, selecting a dense honeycomb core (with smaller cell size) will lead to higher strength; however, this will also lead to an increase in density. Similarly, a thicker skin will increase the bending stiffness of the facing but will weigh higher. Both situations will lead to an increased use of material and added complexity in the manufacturing process, which will result in an increase in cost. Therefore, there will exist a trade-off between the cost and the need for high performance. Figure 12 shows that aluminum honeycomb cores offer superior performance at low cost compared to other sandwich cores.^[24] Apart from the weight and structural design criteria, other secondary requirements, which are equally important, are listed down:

1. Appearance.
2. Corrosion resistance.
3. Piece size availability.
4. Thermal/electrical conductivity.
5. Operating temperature range.
6. Flammability/flame retardant.
7. Formability and machinability.

In conclusion, the primary advantages of using a sandwich honeycomb structure are primarily low weight and structural efficiency. The mechanical advantages are high stiffness-to-weight ratio, high strength-to-weight

ratio, high compression strength, high shear strength, resistant to heat and heat fluctuation, high impact resistance, and damage tolerance. Other contributing factors are the ability to retain a smooth continuous surface even under the applied load and excellent fatigue resistance with almost no stress risers. The critical part that may contribute to fatigue will be the attachment points between the face sheet and the core. Using a sandwich honeycomb structure gives some degree of flexibility in design, as opposed to the conventional structural shape.

Standards for Sandwich and Core structures

A material datasheet of a honeycomb core usually will specify the physical and mechanical properties. The physical property of the honeycomb core is the density, whereas its mechanical properties are usually prescribed as follows:

1. Compressive yield strength, bare or stabilized with facings.
2. Compressive modulus, stabilized with facings.
3. Shear strength in the L and W directions.
4. Shear modulus in the L and W directions.

Bare compressive strength indicates the compressive strength measured without facings, whereas stabilized compressive strength indicates the compressive strength measured with facings attached to the core. The compressive strength is indicated by the ultimate stress (highest stress value), and the compressive modulus is determined by the linear portion of a stress-strain curve obtained from a compression-loaded sandwich panel. The shear strength and shear modulus are obtained similarly from the plane

Fig. 12 Cost versus performance of various lightweight cores^[24]

shear test. They are influenced by the loading directions; therefore, the properties are indicated in the L or W direction. Apart from the density and cell configuration, the mechanical property of the honeycomb panel is also anisotropic (i.e., affected by the direction of loading). The highest compressive and tensile strength of a honeycomb structure is in the T direction. The honeycomb structure provides shear strength in the direction perpendicular to T , which is in the L and W directions. In a hexagonal core structure, the shear properties are highest in the L direction. Comparison of shear strength and shear modulus in the L and W directions for 5056 alloy showed considerable differences as shown in Fig. 13. The OX process tends to increase “ W ” shear properties and slightly reduce “ L ” shear properties, compared to the hexagonal honeycomb core. The shear strength will be almost equivalent in rectangular and square cell configurations. The Cross-core cell configuration is arranged in the biaxial manner so that equal properties are achieved in both directions.

A comparison of typical mechanical properties and other design requirements for some commercially available honeycomb cores is portrayed in Table 6.^[28]

Standard test methods for mechanical and physical properties of sandwich constructions and core structures

can be referred in SAE-AMS-STD-401 or its predecessor military standard MIL-STD-401B,^[36] Sandwich Constructions and Core Materials: General Test Methods. This standard covers testing methods for both core and sandwich constructions used in aircraft structures. Comparable test methods from the ASTM on the same subject matter are referred in ASTM D30.09, Core Material and Sandwich Structure Standards.^[37] Table 7 provides a list of test methods outlined under this standard. The former are more restricted in scope to include tests that are specifically applicable to sandwich constructions for aircraft. According to MIL-STD-401, the test methods for mechanical properties of core and sandwich structures are shear, tension, compression, and flexure. According to Federal Aviation Administration and European Aviation Safety Agency regulations for aircraft construction, honeycomb cores are tested in compression (in-plane and out-of-plane) and also three-point bending. Some useful equations for the basic properties used in the calculation of loads and deflections are given in Table 8. Poisson’s ratio of the honeycomb core is determined by the anticlastic curvature of the core when bent. It cannot be measured in the conventional way due to the simultaneous inward and outward motions of L and W when subject to compressive or tensile load.

Strength of a Honeycomb Composite Structure

For the purpose of designing aircraft parts with aluminum honeycomb sandwich panels, the knowledge of the loading characteristics that the structure has to sustain is necessary.

One of the many loads that an aircraft structure will experience is the bending load. The wing skin, for instance, when the airflow passes over the skin surface, is subject to bending (from pressure differential) and shear loads. The bending loads are further transferred to the primary spar

Table 8 Useful equations for basic parameters

Parameter	Equation
Total mass, m	$m = m_f + m_c$
Cross-sectional area of core, A_c	$A_c = LW$
Average core density, ρ_{ca}	$\rho_{ca} = \frac{8dt_c}{A_c} \cdot \rho_{al} \cong \frac{8}{3\sqrt{3}} \cdot \frac{t_c}{d} \cdot \rho_{al}$
Moment of inertia of facing, I_f	$I_f = \frac{h^3 - h_c^3}{12} \cdot b$
Poisson's ratio, γ	$\gamma = \frac{-R_1}{R_2}$

structures. On a honeycomb panel, the bending load will create tensile and compressive loads at the top and bottom facings. The transfer of these two loads to the core will create an equal and opposite in-plane shear load to the honeycomb core. In a pure bending condition, the bending stress is highest at the top and bottom facings, whereas the stress variation is linear through the thickness of the honeycomb. Therefore, it will be zero at the neutral axis, which is the centroid of the cross section.

Because of the linear distribution of the bending stress, it is more efficient to locate the mass of the structure at the facings. In doing this, the second moment of inertia, I , increases, thus improving the flexural stiffness, EI . Another improvement strategy applied to the aluminum honeycomb sandwich panel is the use of alloy with higher strength and stiffness for the face sheets.

Flexural stiffness of a solid rectangular beam with thickness h and width b is usually described by the following formula:

$$D = EI = E \frac{bh^3}{12} \quad (1)$$

If the beam is constructed from a core with thickness c , sandwiched between two face sheets, then the stiffness can be written as

$$D = E_f \frac{b(h^3 - c^3)}{12} + E_c \frac{bc^3}{12} \quad (2)$$

where E_f and E_c represent the moduli of the face sheets and core, respectively. The second term can be ignored if the core is considered to be extremely lightweight, and stiffness E_c can be neglected. Then Eq. 2 can be rewritten as

$$D = E_f \frac{bh^3}{12} \left(1 - \frac{c^3}{h^3} \right) \quad (3)$$

The amount of facing material can be written as

$$A_f = 2fb = hb \left(1 - \frac{c}{h} \right) \quad (4)$$

The term $\left(1 - \frac{c}{h} \right)$ in the above equation represents the proportion of the facing material to the total material for a rectangular cross section of area hb . Similarly, the term $\left(1 - \frac{c^3}{h^3} \right)$ in Eq. 3 represents the proportion of stiffness in the facing to the total stiffness of the rectangular structure with area hb . Therefore, based on this proportionality, a sandwich that has one-eighth of the weight of solid material (excluding the contribution of lightweight core) can exhibit one-third of the stiffness of the same solid material. An illustration of how the sandwich construction improves on the strength and stiffness compared to a solid construction is given in Table 9.^[28] In a honeycomb structure, the middle portion of the structural mass is removed and replaced with a low-density honeycomb core, resulting in a thicker panel while maintaining almost the same weight. Having the structural mass located at the face sheets will improve the geometric properties, thus tremendously increasing the strength and stiffness.

The structural concept of a sandwich honeycomb panel is therefore to support the in-plane compression and tension in the skins, whereas the axial compression and shear loads are borne by the honeycomb core as illustrated in Fig. 14. With the adhesive rigidly joining the face sheets and the core, the

Table 9 Characteristics of sandwich construction versus solid metal^[28]

	Solid metal sheet	Sandwich construction	Thicker sandwich
			
Relative stiffness	100	700	3700
		7 times more rigid	37 times more rigid
Relative strength	100	350	925
		3.5 times as strong	9.25 times as strong
Relative weight	100	103	106
		3% increase in weight	6% increase in weight

Fig. 14 Loads acting on a honeycomb panel

whole construction becomes one integral unit possessing high torsional and bending rigidity. The previous concept only considers an ideal case in which the skin is responsible for the in-plane loads and the core for the shear loads. However, the contribution of shear stresses in the core is not negligible as observed by Paik et al.^[23] The influence could be disregarded for thin panels with a span-to-thickness ratio of >10 .^[38]

The failure modes of the sandwich panel depend on the mechanical properties of the face sheets and core, the geometrical properties, and the loading arrangement. Under the actions of combination of loads, the possible failure modes can be categorized into five main categories:

1. Excessive deflection under bending.
2. Buckling of the thin skin due to the bending loads.
3. Buckling/collapse under in-plane (axial) compression.
4. Crushing of core under lateral pressure.
5. De-bonding between the thin skins and the core structure.

To understand the mechanism of these failure modes, three types of tests can be carried out: flexural, compression, and shear tests. The buckling and collapse under axial compression of both the skin and the core requires a test setup in which a simply supported sandwich panel is loaded in a direction parallel to the sides of the panel. The parameters for the testing can be the panel aspect ratio and the panel thickness other than the cell configurations.

For lateral crushing, some of the examples that can create this effect are from the impacts due to slamming, collision, sudden concentrated loads (e.g., from dropped tools), and hydrostatic pressure. In this instance, the deformation that arises can be considerably larger, contributing to the folding of the panel itself and cell walls to be compressed together. To analyze this behavior, the energy absorption capacity of the panel can be experimentally studied, and the magnitude of the damage can be estimated. An instrumented load is imposed on a flat sandwich panel under simply supported boundary conditions at a rate that can be controlled. The loading rates can be quasi-static in nature ranging from low- to high-velocity impact. De-bonding of the skin and core can occur in any loading conditions stated previously. Examples of bending deflection and axial buckling are shown in Fig. 15.^[23]

Fig. 15 (a) Bending deflections and (b) buckling due to axial compression^[23]

The strength of the honeycomb composite structure under combined bending and shear loads is determined by the capability of the facings to resist in-plane tension or compression and compression, whereas the core material and the adhesive must resist shear. Sections “Flexural Test”, “Shear Test”, and “Compression” describe the three standard tests that are used to evaluate the strength and stiffness of the sandwich structure and core materials. The general standards for testing the core and sandwich construction primarily of the types used in aircraft structures can be found in MIL-STD-401.

Flexural Test

To analyze the bending characteristics of a sandwich panel, a flexural test is required. Flexure tests on a sandwich panel can be used to determine the sandwich flexural stiffness, the core shear strength, and the shear modulus or the facings’ compressive and tensile strength. However, the strength and stiffness of the core can be obtained more accurately using the core shear test methods defined by MIL-STD-401 or ASTM C-273. To determine the shear properties of the core, the facing must be sufficiently thick and/or the support span sufficiently short to avoid facing failures. Facing failures can be caused by the compression and tension loads or by localized wrinkling at load points or reactions. Figure 16 shows the schematic of the flexural test setup that caters for identifying the core and facing properties prescribed by ASTM C-393.^[40]

Fig. 16 Long- and short-beam bending loading^[41]

Under both conditions of loading, the calculations of flexural properties for sandwich panels and core material can be written as follows:^[41]

Core shear strength

$$\tau = \frac{P_1}{(d+c)b} \quad (5)$$

Facing bending stress

$$\sigma = \frac{P_2 L_2}{4t(d+c)b} \quad (6)$$

Short-beam midspan deflection

$$\Delta_1 = \frac{P_1 L_1^3}{48D} + \frac{P_1 L_1}{4U} \quad (7)$$

Long-beam midspan deflection

$$\Delta_2 = \frac{11P_2 L_2^3}{768D} + \frac{P_2 L_2}{8U} \quad (8)$$

If D is unknown and cannot be computed from Eq. 2, then the flexural stiffness and core shear modulus can be calculated based on the deflections of the midspan for the short and long beams.

Facing flexural stiffness

$$D = \frac{P_1 L_1 \left[1 - \left(\frac{11L_2^2}{8L_1^2} \right) \right]}{48\Delta_1 \left[1 - \left(\frac{2P_1 L_1 \Delta_2}{P_2 L_2 \Delta_1} \right) \right]} \quad (9)$$

Core shear modulus

$$G = \frac{P_1 L_1 C \left[\frac{8L_1^2}{11L_2^2} - 1 \right]}{\Delta_1 b(d+c)^2 \left[\left(\frac{16P_1 L_1^3 \Delta_2}{11P_2 L_2^3 \Delta_1} \right) - 1 \right]} \quad (10)$$

Figure 17 shows the possible failure modes from three-point bending.^[42] Face yielding occurs for metal face sheets, whereas face microbuckling occurs for composite face sheets. Face yielding is the plastic collapse of the metal face sheets when the axial stress of the specimen exceeds the yield strength of the material, whereas microbuckling occurs when the axial stress exceeds the microbuckling strength. Face wrinkling can be considered as buckling of compressive sheet that is supported between two reaction pins. Mode A represents the core shear over the full span of the beam, whereas mode B represents the core shear

Fig. 17 Possible failure modes from three-point bending^[42]

over the central portion only. The indentation failure mode is characterized by three plastic hinges formed at the top face sheet near the central indenter.

Shear Test

In a shear test, the core or sandwich specimen is bonded to heavy steel plates at both core ends, and then tensile or compressive load is applied at a constant rate (refer Fig. 18) that will cause shear. Core shear properties can also be obtained from a sandwich flexure test as described in "Flexural Test" section. Comparable ASTM test method is the ASTM C273,^[43] which is the standard test method for shear properties of core materials. This test is to determine the shear strength parallel to the plane of the sandwich and shear modulus associated with the distortion in the plane normal to the sandwich facings. The shear specimen with loading is illustrated in Fig. 18.

Shear stress and shear modulus are calculated by the following equations:

Core shear stress

$$\tau = \frac{P}{Lb} \quad (11)$$

Core shear modulus

$$G = \frac{St}{Lb} \quad (12)$$

where S is the slope of the initial portion of load–deflection curve, L is the length of the core, and t is the thickness of the core.

From this test, the desired failure mode is 100% shear failure of the core. If cohesive failures of the core-to-plate adhesive or adhesive failures to the core or plates occurred, then the results of that specimen should be neglected.

Fig. 18 Shear test setup^[36]

Compression

Compression of the core and sandwich can be in the direction normal to the facing, termed as flatwise compression, or can be parallel to the facing, usually termed as edgewise compression. The flatwise compression test involves subjecting the sandwich core specimen to a uniaxial compressive force in the loading direction normal to the plane of the facings of the sandwich construction. Comparable ASTM standard for core and sandwich flatwise compression is ASTM C365. Loading is applied through a suspended spherical loading platen at a rate that can produce failure within 3–6 min, and if there is no definite maximum load, then the maximum load is recorded at 2% strain. In the edgewise compression, the loading direction is parallel to the facings of the sandwich construction, and the standard test method is prescribed by ASTM C364. The edgewise compression strength provides a basis for judging the load-carrying capacity of the sandwich construction in terms of the developed facing stress. Figure 19 shows the flatwise and edgewise compression setups.

Data obtained in terms of load–deflection curve can be used to calculate the compressive stress at the proportionality

limit, the compressive strength, and the compressive modulus. The edges are normally stabilized to avoid local crushing of the sandwich core; therefore, it is customary to report the compression parameters as bare or stabilized. Calculations of the compression properties per ASTM C365 for the flatwise compressive parameters are as follows:^[44]

Flatwise compressive strength

$$\sigma_{cu} = \frac{P_{\max}}{A} \quad (13)$$

Flatwise compressive modulus

$$E_c = \frac{\Delta P/A}{\Delta \epsilon} \quad (14)$$

In the calculation of the compressive modulus, the load and strain values shall represent the lower part of the stress–strain curve.

Edgewise compressive strength

$$\sigma = \frac{P_{\max}}{w(2t_f)} \quad (15)$$

Fig. 19 (a) Edgewise and (b) flatwise setups

For edgewise compression tests, the failures are usually composed of a type of buckling failure. The buckling failures can manifest by wrinkling of the facing, shear crimping, dimpling of facings, or general buckling as shown in Fig. 20. The buckling failure modes can be avoided by observing some basic design principles. To avoid the failure of the core, the core thickness should be sufficiently thick to carry the shear stresses. It should have enough shear rigidity to avoid local buckling; the sandwich facings should be at least thick enough to handle the stresses at the design loads; the sandwich core should possess enough modulus of elasticity to keep itself strong; and for a honeycomb core used in airframes, the cell size should be small enough to avoid failure.

MANUFACTURING PROCESS OF HONEYCOMB PANEL

The standard requirements for the manufacture and assembly of a bonded honeycomb panel are provided in

MIL-HDBK-349.^[31] A general flowchart describing the steps of manufacturing adhesively bonded honeycomb panel assemblies is given in Fig. 21. The overall process flow starts with preparation and processing of the three main components—the adhesives, the honeycomb core, and the skin—followed by application of adhesives, assembling, and curing.

Honeycomb Core

The most important part of manufacturing an aluminum honeycomb composite structure is the manufacturing process of the core itself. For the aluminum alloy skin, unless otherwise specified in the material and process specification, parts may be formed from aluminum sheets or extrusions in the tempered condition at ambient temperature. Parts may be cooled for cold forming by chilling on dry ice or in a cold box to the temperature specified on the engineering drawing. This will be followed by the preparation of the three main components for the panel assembly.

Fig. 20 Possible failure modes under edgewise compression.^[36] (a) General buckling; (b) shear crimping; (c) dimpling of facings; (d) wrinkling of facings

Fig. 21 General manufacturing process flow of a bonded honeycomb panel^[31]

The manufacturing cost of an aluminum honeycomb is relatively inexpensive as less material is required, and the overall manufacturing process can be considered relatively simple. Because it is generally considered as soft metal, aluminum alloy has good malleability and formability, and therefore can be cold worked to produce the honeycomb core. The manufacturing process of the honeycomb core is largely determined by how the nodes of the honeycomb can be attached. There are five ways to do the process: adhesive bonding, resistance welding, brazing, diffusion bonding, and thermal fusion.^[6] Almost 95% of the honeycomb produced is using the adhesive bonding technique, and the manufacturing processes associated with this technique are traditionally called the expansion

process and the corrugation process.^[6] The majority of the honeycomb produced is manufactured using the expansion process. The expansion process best uses low-density honeycomb materials, whereas the corrugation process uses higher density honeycomb materials. The general rule is that the corrugation process will be used if an aluminum honeycomb core with a density $>192 \text{ kg/m}^3$ is required.

Expansion

The expansion process flow is shown in Fig. 22. Aluminum foil sheets are first cut from rolls of materials and cleaned. Most applications require the surface to be treated for corrosion. This usually involves application of

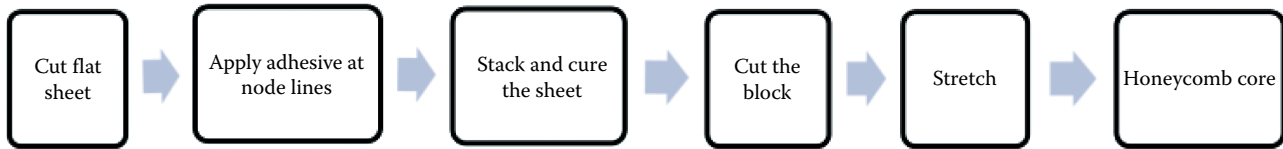

Fig. 22 Process flow for the expansion process

a corrosion-inhibitive coating to the cleaned surface of the foils. The surface coating improves the bonding of the aluminum sheets. Prior to the application of the adhesive, the foils may require perforated or non-perforated treatment. The purpose is to create small pinholes in the foil that will allow gas buildup to escape during the curing process. The foils are then printed with adhesives applied at the intervals (node lines) on their surface. Then they are cut into slices and closely stacked into piles using a stacking machine. The adhesives are cured using heated press, and this process will bond the stack of foil sheets together at the node lines to form a block of honeycomb, called honeycomb before expanded (HOBE).

The HOBE block is the finished product that can be supplied directly to the customer. The unexpanded block is compact, occupies minimal space, and costs less for shipping with lower risk of damage compared to the expanded version. Usually, however, the blocks are cut into individual unexpanded slices where the thicknesses depend on the customer requirement. Unexpanded core block (CUE) is sawed into smaller slices or wedges using a band saw. Unexpanded cut slices with a large cell size or thinner slice can be easily expanded into their full sheet form, without the need for sophisticated equipment.

In aircraft applications, the expanded core version is more often used. Blocks can be expanded to regular hexagons, under-expanded to six-sided diamonds, and OX to nearly rectangular cells, and then are cut to the desired thickness. The OX cell shape allows the core to flex in one direction easily, making it suitable for forming simple curves. By varying the degree of pull in the expansion process, regular hexagon-shaped cells or OX cells can be produced, each with different mechanical and handling/drape properties. Due to this bonded method of construction, a honeycomb will have different mechanical properties in the 0° and 90° directions of the sheet.

Additional customer requirements may include drilling the unexpanded cores, thus allowing air to flow between the cells upon expansion. Figure 23 illustrates the manufacturing flow of the expansion process.^[18]

Fig. 23 Expansion process^[18]

The heated press technique is suitable if the application dictates the use of simple flat panels. For large, curved, and complex panels, the vacuum bagging method is the preferred method. This method provides the flexibility in terms of shape and size of the honeycomb cores.

The cutting of HOBE is done with horizontal or vertical band saws using special honeycomb blades. The saws usually have a vacuum system due to the large amount of dust produced from the core material.

Corrugation

The process flow of the corrugation method is illustrated in Fig. 24. This method is the original technique used to fabricate the honeycomb core. Although it is labor intensive, this method is still used for making high-density metallic and some nonmetallic cores.^[6] Contrary to the expansion process, the corrugation process introduces preformed corrugated sheets prior to applying the adhesive, and therefore eliminates the need for expansion. In the corrugation process, the foil substrate first passes through a pair of corrugated rollers that are specially designed to manufacture the honeycomb, becoming a corrugated sheet. Basically, the sheets are pressed into half-hexagonal shapes, the profile with adhesive is applied to the corrugated points, the sheet is then cut into the desired dimension (length), and

Fig. 24 Process flow for the corrugation process

Fig. 25 Corrugation process^[18]

the adhesive is applied to the node lines. The corrugated sheets are then stacked into blocks and cured. Figure 25 illustrates the manufacturing process for the corrugation technique.^[18] Since only light pressure can be applied to the stacked block, the node adhesive is much thicker than the expanded core. In fact, the node adhesive can be 10% of the total honeycomb weight, whereas it is only about 1% or less in the expanded core.

Both of these manufacturing methods offer a range of cell configurations for different requirements such as formability, curving, energy absorption, and strength. The corrugation process is more complex and time consuming compared to the expansion process. Hence, the corrugated honeycomb core is usually more expensive. The corrugation process is preferred though, if the density of the core exceeds 192 kg/m³ (12 pcf) due to the difficulty in expanding the HOBE. The force to expand the block or slice is too great for the nodes to hold the block. Another advantage is that the heavier and stronger corrugated core does not crush easily compared to the lighter expanded core. The crush stroke of the corrugated core is between 60% and 70% compared to 70% and 80% of the initial height of the expanded core.

Phosphoric Acid Anodized Honeycomb Aluminum honeycomb composite structures are known to be susceptible to corrosion of the core cells due to moisture that seeps in, and this poses serious in-service durability problems. In extreme cases, the assembly of the sandwich structure was reduced to two face sheets with almost hollow core. In 1977, Boeing patented a process to introduce a corrosion-inhibitive coating that can improve the durability. The coating process was costly then, and it was not until later in the 1990s that Hexcel took up in developing the coating further. Hexcel's CRIII and Alcore's Dura-core are two examples that implement such coating system.^[6]

A polymeric film is applied to the surface of the aluminum sheet using a phosphoric acid anodizing process prior to the application of the adhesive in the expansion or corrugation process. The phosphoric acid anodizing process works in two ways. First, it creates a microporous oxide structure on the surface that practically increases the surface area of attachment of the corrosion coating. Second, it protects the surfaces of the aluminum honeycomb

structure from corrosion and also slows down environmental degradation. In addition, the corrosion coating also strengthens the core-to-face sheet bonding by improving the fillet configuration.

Other Processes

The previous two processes are considered as labor-intensive batch processes. Other processes used for producing the honeycomb core that are worth mentioning and not restricted to aluminum honeycomb are briefly described as follows:

1. Expansion and corrugation processes for thermoplastic honeycomb

The expansion and corrugation processes can also be applied to thermoplastic honeycomb with a slight variation in the way the nodes are bonded together. Instead of applying adhesive to the nodes, the bonding is achieved by heat fusing the nodes together. When HOBE block is expanded, the expanded core is further heat set to retain the expanded shape.

2. Extrusion process

In 1974, R.D. Bagley patented the extrusion method for forming thin-walled honeycomb structure (US 3790654 A).^[45] This invention is applicable for extrudable materials such as ceramic batches, molten glasses, plastic, molten metals, and similar materials, which have the property of being able to flow or plastically deform during extrusion while being able to become sufficiently rigid immediately thereafter so as to maintain structural integrity. The flow of the extrusion process is illustrated in Fig. 26.^[46] The material to be extruded is normally in the form of powder, which has been plasticized to give favorable extrusion performance. The quality of the extrusion mass before extrusion is the main key to produce high-quality honeycombs.^[47,48] After extrusion, the honeycomb cores are dried and then undergo heat treatment to achieve the desired strength and characteristic. The production of better honeycomb cores requires extrusion dies with finer structures.

3. Folded honeycomb^[49,50]

The concept of a folded honeycomb is derived from the corrugated cardboard production. For example, inserting three 90° bends that quarter a honeycomb panel will form the walls of a square box. Figure 27 illustrates a single continuous sheet that is subjected to various in-line finishing techniques including cutting, folding, and gluing.^[50] This technique results in a high-speed and low-cost production of the core.

4. Strip slotting technique^[50]

This technique is used specifically for producing a square or a triangular honeycomb as shown in Fig. 28. In this process, no bending is required; therefore, it

Fig. 26 Extrusion process^[46]

Fig. 27 Continuous process of folding a honeycomb^[50]

is suitable for less ductile materials. The strips are cut into predetermined lengths, and a honeycomb is assembled by positioning the strips cross-wise of each other with the slots of one strip facing those of one another. The slots of one strip are engaged with those of a cross-wise strip, where the strips are interlocked with each other forming a plurality of cells in the form of a honeycomb.

Application of Adhesive

Production techniques and equipment for adhesive bonding are much more elaborate than those for conventional fastening. Jigs and fixtures must be designed to ensure the intimate contact of the substrates over the entire surface and to provide sufficient heat during the assembly and cure of five joints. Since bonding is purely a surface phenomenon, surface preparation is more demanding than for mechanical fasteners. In general, adhesives function more effectively in thin sections. As these sections become thicker, the adhesive-to-metal strength ratio is lowered.

Prior to adhesive bonding, the adhesive primers are applied to cleaned part surfaces to mostly improve bonding and durability. As adhesives are usually in the form of

foams or films, bonding techniques will differ depending on tooling and assembly requirements. Adhesives are also temperature sensitive; therefore, their handling and processing must be done within the allocated time frame once they are removed from the refrigerated storage.

The application of film adhesive is usually performed in the following manner: Film adhesive can be one sided or two sided. When an adhesive has a protective film on both sides, the protective film on one side is removed before applying the film, and the protective film on the other side is removed just prior to assembly. When a film adhesive has only one protective film, the protective film is left on the detail until it is ready for assembly. Adhesive film is placed on one or the other interface of each bond joint. The film is then pressed firmly in place and carefully smoothed out. Some films require heat tacking to hold them in place. Finally, the excess film is carefully trimmed off.

For foam adhesives, these are mostly used when relatively large gaps (0.005–0.125 in.) have to be closed in order to bond two surfaces together.^[31] This is possible due to the expansion of the adhesives during curing and release of gas, such as nitrogen. They are mostly used for core-to-core and core-to-edge member or inserting bonds. Method of application is simply by applying one layer to

Fig. 28 Strip slotting technique for (a) a square honeycomb and (b) a triangular honeycomb.^[49] For a square honeycomb, the strips are arranged at 90° , whereas for a triangular honeycomb, the cross-wise angle is 60° .

the cleaned part surfaces, and any additional layers can be further added according to the structural or geometric requirements.

Panel Assembly

The assembly involves the process of joining the face sheets and the honeycomb core. Optimal bonding of the core to face sheets is obtained by maintaining the glue resin viscosity. This whole process is rather critical and costly, and may yet produce a bond that is de-bonding sensitive. Bonding of face sheets to the core material can be performed in a single stage or two-step process. The former is a one-step or co-curing method in which the skins are laid up and applied to the core, and then the sandwich assembly is cured and bonded in one autoclave process. The latter is a two-step operation in which the skins are laid up and cured independently prior to bonding to the core material and cured.^[26] The advantage of co-curing is that it produces higher quality sandwich panels with equal structural integrity and at the same time provides considerable cost savings. In special cases of complex core machining and forming, bonding only one face sheet at a time is desirable. For example, one side of the core is machined and the skin is bonded to the core in a formed mold, and then the other side of the core is machined in the restrained position and co-cures the second face sheet.

The curing process involves introducing pressure and heat to activate the adhesives in the bond lines and bond the whole assembled parts. Therefore, control of pressure and curing temperature is crucial and usually dictated by

the type of adhesives used, the type of honeycomb, and the type of assembly.^[26] Number of cure cycles can also vary according to the type of assembly. Some parts require sub-assemblies prior to the whole part assembly, which means more than one cure cycle is used. For example, trailing edge panels require multiple cure cycles compared to laminated edge honeycomb panels that only require a single cure cycle.^[26]

SUMMARY

This article briefly describes the design and manufacturing aspects involved in aluminum honeycomb composite structures particularly in aerospace applications. Types of aluminum alloys applicable for aircraft and space applications are described in terms of mechanical properties and functions. Design requirements and considerations in selecting core configuration are also highlighted. The flow of the manufacturing processes typically associated with production of aluminum honeycomb core is also discussed.

Hot Stamping of Complex-Shaped High-Strength Aluminum Components

Liliang Wang, Jun Liu, and Jianguo Lin

Department of Mechanical Engineering, Imperial College London, Exhibition Road, London, SW7 2AZ, United Kingdom

Abstract

Aluminum alloy components are important contribution to lightweight transportations for improving energy efficiency. However, formability of aluminum alloys at room temperature often hinders their further applications in the automotive, rail, or aerospace industries. The solution heat treatment, forming, and in-die quenching (HFQ®) process is an advanced forming technology that performs both forming and heat treatment simultaneously in a single operation. Since its inception, a significant amount of research has been made on the process to develop it further and to assess the feasibility of using it to form components with increasingly complicated geometries, from a growing variety of alloys. This entry summarizes the HFQ® research work, with the emphasis on the development, modeling, and applications of the technology for stamping complex-shaped high-strength aluminum panel components.

Keywords: Aluminum alloys; Constitutive modelling; FE simulation; Forming limit; Hot stamping; Lightweighting; Viscoplasticity.

INTRODUCTION

Due to the increasing demands for high fuel efficiency and low emissions in land and air transportations, weight reduction has become one of the major priorities of research, engineering design, and manufacturing. The use of aluminum has been increasing rapidly in recent decades to achieve desired weight saving without jeopardizing the structural integrity of the products. Although aluminum alloys have great potential for producing complex-shaped high-strength components with reduced weight, the alloys have limited formability at room temperature and require special processing techniques.

Age-hardening aluminum alloy sheet components are normally cold formed either in the T4 condition (solution heat treated and quenched), followed by artificial aging for higher strength, or in the T6 condition (solution heat treated, quenched, and artificially aged). Either condition introduces a number of intrinsic problems, such as spring-back and low formability, which are difficult to solve. Hot stamping can increase formability and reduce spring back, but it destroys the desirable microstructure. Postforming heat treatment, such as solution heat treatment (SHT), is thus required to restore the microstructure, but this operation results in distortion of the formed components during quenching after SHT. These disadvantages are also encountered in forming engineering components using other materials. In an effort to overcome these disadvantages,

various efforts have been undertaken and special processes have been invented to solve particular problems in forming particular types of components. SHT, forming, and in-die quenching, or HFQ®, is a novel hybrid-forming process that was developed to enable the production of complex-shaped lightweight components from aluminum alloys. This entry will explore the development of HFQ® technology, introduce an advanced material modeling technique for hot stamping, and demonstrate the applications of the HFQ® in transportation industries.

HFQ® PROCESS

Heat treatment is required for the structural aluminum alloys to achieve desired microstructure and thus specified mechanical properties. Previous studies have shown that heating a material to its SHT temperature, e.g., 450°C–550°C, significantly increases its formability, due to the complete dissolution of alloying elements and/or precipitates into the material matrix resulting in a single phase, which reduces the obstructions to dislocation motion and enhances material flow.^[1] This material characteristic has been utilized for the stamping of complex-shaped high-strength aluminum panel components that has led to the formulation of the HFQ® process.^[2] Depending on the particular aluminum alloys, the HFQ® has been divided into one-stage forming^[2] and two-stage forming.^[3]

HFQ® is particularly useful for the stamping of high-strength aluminum sheets, since the ductility of high-strength aluminum is very low at ambient temperature. The HFQ® process mainly consists of four phases, as illustrated in Fig. 1.

Solution Heat Treatment

An aluminum blank sheet is heated to its SHT temperature and is maintained at that temperature for a specified period of time until all the constituents are taken into solid solution, giving one single phase. The SHT fully dissolves the existing precipitates from the previous processes and uniformly distributes the alloying elements within the aluminum matrix. For Al-Mg-Si alloys, these precipitates are mainly composed of Mg_2Si and/or Si. The presence of these precipitates increases the strength of the material, but reduces the ductility.

Dissolution of the precipitates (Mg_2Si) is clearly evidenced by the scanning electron microscopy (SEM) micrographs in Fig. 2.^[4] At the start of the treatment in Fig. 2a, the solutes are in patches of highly concentrated alloying elements (precipitates) of different size that provide barriers to the flow of the material during deformation. With

time, these precipitates dissolve within the aluminum matrix, diffusing throughout the whole structure (Fig. 2b). This diffusion results in the “flow barrier” being reduced and eliminates the chance of forming micro-voids around second phases in plastic deformation. This will eventually increase the ductility of the material but reduce the strength. Holding the material at the SHT temperature for a sufficient time (Fig. 2c) will also allow such factors as irregular precipitates and residual stresses to be further reduced, leading to homogeneous microstructure throughout the whole aluminum matrix, and hence a more formable material.

A typical operation temperature for the SHT is most preferably within the range 450°C–550°C depending on the alloy series. A typical time for the SHT varies from 20 to 60 min, e.g., 30 min. The heating furnace can take the form of a roller hearth furnace, or a multilayer feeder furnace, which is more space efficient. Multiple sheets are heated simultaneously to reduce the forming cycle time.

Transfer

After the SHT, the blank is immediately transferred via feeder arms to the cold (room temperature or slightly above) dies that are assembled in a press. The transfer of

Fig. 1 Schematic diagram of the HFQ® process

Fig. 2 SEM micrographs showing the evolution of Mg_2Si precipitates within the aluminum matrix at solution times of (a) 5 min, (b) 25 min, and (c) 50 min^[4]

the blank should be controlled in a matter of seconds. The operation time should be less than 5 s and preferably less than 3 s. The feeder may provide heat protection in the form of a thermal chamber installation so that heat loss from the blank is minimized.

The tools are cold to ensure that the blank is quenched at a sufficiently rapid rate during the forming and the subsequent holding stage. High forming speeds are normally utilized to enhance the strain rate hardening of the material, to minimize the amount of heat transfer to the dies prior to the completion of the forming, and to ensure that the blank maintains its temperature and therefore its formability. In the single-action tool sets, the die comprises a male part and a female one, and the component is “crash-formed” by the action of a punch toward the female die. In the double-action tool sets, a blank holder or binder is also used that clamps the material in the blank holding area before deforming the blank. The benefit of such an operation is that the excessive wrinkling is avoided by limiting the extent of material draw-in; however, careful control of the forming parameters is essential to prevent the localized thinning as a result of excessive plastic deformation in the side walls of the component.

Cold Die Forming and Quenching

The blanks are stamped into the die shape, and the formed component is held in the cold dies for a period of time

under an appropriate holding force to quench it to a sufficiently low temperature. The rate of quenching must be fast enough to prevent second-phase particles (i.e., precipitates) from coming out of the solution and to attain a supersaturated solid solution (SSSS) microstructure, which is required for the artificial aging in the case of heat-treatable alloys.

The precipitation behavior during cooling from SHT of Al-Mg-Si alloys has been investigated over a wide range of cooling rates by Milkereit et al.^[5] The microstructural evolution of an EN AW-6005A is shown in Fig. 3 using micrographs obtained through optical microscopy and transmission electron microscopy (TEM). Coarse precipitates (mainly Mg_2Si with a few microns in size) were observed as dark particles by optical microscopy, and they were homogeneously distributed in the aluminum matrix, as shown in Fig. 3a. The sizes of such precipitates decrease as the cooling rate increases (Fig. 3a–c). These precipitates were hardly detected by optical microscopy when the cooling rate was over $10^\circ\text{C}/\text{min}$. Much smaller precipitates were therefore examined by TEM, and they were visible in rod- and lath-shaped phases at cooling rates of up to $100^\circ\text{C}/\text{min}$, as shown in Fig. 3d–f. However, almost no precipitation can be found by TEM at the cooling rate of $375^\circ\text{C}/\text{min}$.

A critical cooling rate is required during the HFQ® process to attain maximum supersaturation after quenching and ensure maximum strength after aging. For instance, a maximum hardness value for EN AW-6005A

Fig. 3 Microstructures of EN AW-6005A samples after cooling at different rates: (a)–(c) optical microscopy and (d)–(f) bright-field TEM^[5]

was reached only when a complete SSSS microstructure was attained at a quenching rate of 375°C/min.^[5] The heat transfer from the formed component to the dies can be enhanced by increasing the holding pressure.^[6] Dies can also be used that contain cooling channels, to prevent them from heating up and maintain them at a low temperature, particularly over multiple forming cycles. The holding of the closed die during quenching prevents distortion of the formed component.

Postforming Heat Treatment

The HFQ® process may comprise a post-forming heat treatment stage for heat-treatable aluminum alloy components that includes heating the formed component to an artificial aging temperature and holding it at that temperature to allow the precipitation hardening to occur. Typical temperatures range from 120°C to 250°C. Typical aging times are in the range of 5–48 h.

The age-hardening responses of aluminum alloys are very significant, and hence control of precipitation during the postforming heat treatment is critical for attaining optimal material performance. Figure 4 shows the bright-field TEM microstructures of an Al-Mg-Si alloy at different stages of artificial aging. The predominant precipitates in the underaged condition (10 min at 175°C in Fig. 4a) were the very fine precipitates of unknown structure that produced only a small amount of hardening contribution to the hardness.^[7] As aging progressed to 0.5 h at 175°C (Fig. 4b), the precipitates gradually grew and became predominant in the microstructure. The short precipitates, which were regarded as β'' phase, was measured to be approximately 7 μm in length. The aging treatment substantially increased the hardness of the alloy as a result of the increasing fraction of the precipitates. Peak hardness of the material was obtained at an aging treatment of 175°C for 4 h. The precipitate, as shown in Fig. 4c, was thus responsible for the peak age-hardening effect. The

lengths of the precipitates in this stage ranged from about 10–15 μm . Further aging treatment on the alloy would produce overaged microstructure, as shown in Fig. 4d. The precipitate was recognized as B' phase, which was considered to be responsible for the degradation of hardness that occurred upon over-aging.

Heat-treatable aluminum alloys that are suitable for use in the HFQ® process include those in the 2xxx, 6xxx, and 7xxx series. Specific examples include AA6082 and AA6111,^[8,9] which are commonly used for automotive applications, and AA2024 and AA7075,^[10,11] which are used for aircraft wing structures. Non-heat-treatable aluminum alloys that are suitable for use in the HFQ® process include those in the 5xxx series such as AA5754,^[12] a solution hardening alloy that can benefit from the process in increasing its corrosion resistance.

TYPICAL FEATURES OF HFQ® PROCESS

The HFQ® process has been developed with an aim of addressing two main problems encountered in forming complex-shaped aluminum alloy parts by conventional means:

- The formability of aluminum alloys when cold formed (at room temperature) is very low. Therefore, forming complex-shaped panel components, such as those required for vehicle bodies and aerospace structures, is difficult.
- Springback is very high in cold-formed aluminum components due to the low stiffness of the material. This makes compensation for springback through proper tool and process design, which are very difficult and time-consuming.

The above problems can be effectively solved by implementing the HFQ®. The material ductility can be significantly

Fig. 4 TEM micrographs of precipitate dispersions at different stages of artificial aging: (a) underaged, 10 min at 175°C, (b) underaged, 0.5 h at 175°C (c) peakaged, 4 h at 175°C, and (d) overaged, 20 h at 200°C^[7]

enhanced at a SHT temperature, which is close to that in superplastic forming (SPF). Furthermore, the sheet material can be stamped into the die shape and the localized thinning arising in SPF is much reduced in the HFQ®. The HFQ® process is characterized by low forming loads and high forming speeds, e.g., 250 mm/s, as the blank is much softer at the SHT temperature, and a higher rate of deformation is required to increase strain rate hardening and minimize the onset of localized thinning.^[13] As a result, the productivity of HFQ® is much higher than that of conventional SPF.

The HFQ® process combines both forming and heat treatment in a single operation as the blank is stamped and held between cold tools in order to quench the component to room temperature. In addition to the limited springback, the preservation of the SSSS microstructure during quenching avoids the needs to solutionize the component at an elevated temperature after the forming, which could also cause thermal distortion. HFQ® therefore takes advantage of this material property to enhance the formability and maintain the material microstructure to produce high-strength components efficiently.

This patented HFQ® process is currently being commercialized by the Impression Technologies Ltd.^[14] and has been receiving a considerable amount of interests from industry partners.^[15] Compared to conventional sheet metal forming techniques, it has a huge potential to form large complex-shaped components at high processing speeds, particularly for components that are conventionally assembled from multiple parts, while maintaining favorable postform mechanical properties and minimal thermal distortion and spring back. The benefits provided by the process with regards to an environmental impact has been extensively studied, suggesting that the HFQ® applications could lead to an overall net environmental benefit,^[16] compared to other conventional production methods.

APPLICABLE MATERIALS

Generally, the HFQ® is suitable for forming aluminum and magnesium alloys, and both heat-treatable and non-heat-treatable sheet alloys are applicable in this process.^[17]

In terms of heat-treatable aluminum alloys, 6xxx alloys have been previously formed successfully using the HFQ®,^[18–20] while a slight modification of the process was required to form 2xxx and 7xxx series alloys successfully.^[10,21,22]

For 6xxx series aluminum alloys, it is known that the ductility of the material is obtained from the SHT condition, and the strength is obtained from the aging process.^[23] Achieving a solid solution before forming also ensures that the microstructure attained is conducive to a high post-form strength potential. If the quenching is fast enough during stamping and holding between the cold tools, then the alloying elements will be retained within

the aluminum matrix as the material cools down to room temperature, and a SSSS will form.^[18] Subsequent artificial aging processes is employed to improve the strength of the formed component through the controlled and fine dispersion of precipitates.^[4]

In the case of 2xxx and 7xxx series, such as AA2024^[10] or AA2060,^[22] where the maximum ductility or formability is attained at a temperature lower than the SHT point, it would have to be formed in two stages.^[3] For the first stage, the AA2060 sheet was heated up to the forming temperature (470°C), which is below the SHT temperature (typically around 520°C). After the hot blank was transferred to the cold tool, the stamping process was activated immediately. The transfer time from the furnace to the cold die was controlled to be within 10 s. For the second stage, the formed part was transferred to the furnace and reheated up to its SHT temperature (520°C). After soaking at the SHT temperature for 1 min, the hot component was placed back to the die shape and subsequently quenched to room temperature by the cold tools. The evaluation of post-form strength of HFQ® formed components after artificial aging has verified that the full mechanical properties can be retained after the HFQ® process.

Although the HFQ® is applicable for heat-treatable alloys due to their precipitation hardening mechanism, the process does also have advantages when it is used to form non-heat-treatable aluminum alloys, such as 5xxx series alloys, as has been reported by El Fakir et al.^[12]

Interest in sheet magnesium alloys, which are the lightest structural metals available with a density 30% less than that of aluminum, has recently increased, and these were also found to be applicable for use in the HFQ® process. The non-heat-treatable magnesium alloy AZ31 has been formed successfully, while the trials were conducted on both a fine-grained commercially available rolled alloy and the alloys produced by twin roll casting in laboratory scale.^[24,25] Magnesium alloys, in particular, have limited formability below 200°C. It was found that they could only be feasibly formed close to their SHT temperature as required by the HFQ® process, although the formability of magnesium alloys is lower than that aluminum alloys.

The hot form-quench processes have also been utilized for steels in addition to aluminum alloys; however, the material phenomenon employed in the process differs to each other.^[26] In the case of aluminum alloys, the material is heated to its SHT temperature before forming, while steels are heated to their austenitizing temperature in order to enhance the formability of the material. For heat-treatable aluminum alloys, strengthening is achieved by a fine dispersion of precipitates in the aluminum matrix, whereas for steels, quenching the component as it is being formed at a fast enough rate transforms the austenite phase into a stronger martensite.

The key feature of HFQ® process is to enable the SHTed and stamped component to be quenched in cold die. Thus, the cooling rate is critical to avoid precipitates

Fig. 5 CCP diagram of AA7150 after SHT at 480°C for 60 min^[27]

to be nucleated, particularly at grain boundaries. Figure 5 shows a typical continuous cooling precipitation (CCP) diagram for AA7015. The solid lines indicate the measured precipitation region, while dashed lines represent the precipitation region extrapolated on the basis of dilatometer results toward faster or slower cooling rates. The CCP diagram provides the main phase transformation that may occur at different cooling paths. As different phases will lead to significant variations in properties, it is important to find an optimum way of quenching the heat-treatable aluminum alloys from SHT temperature without losing excessive solute. According to the CCP diagram, it is seen that at a cooling rate of 1°C/s, the main precipitates appears to be MgZn₂ phase. This is also evidenced by means of SEM observations.^[27] Due to the complexity of precipitate transformation, at a cooling rate of 100°C/s, only low temperature precipitates (labeled LT-η') might be present, although the possibility of other heterogeneous nucleation phenomena is still not ruled out. When the cooling rate is over 300°C/s, almost all the precipitates have been dissolved and so that there is no further change in the microstructure.^[27]

ADVANCED MATERIAL MODELING AND FINITE ELEMENT SIMULATION

Unified Constitutive Equations for HFQ® Aluminum

Mechanical properties of hot-formed workpiece are largely dependent on the microstructure and its variation over the workpiece. The simulation of a hot stamping process presents many challenges, as the deformation of the workpiece in addition to its temperature evolution due to heat transfer with the tooling has to be modeled. As can be seen in Fig. 6, the ductility of the material increased and the flow stress decreased with rising temperature. This was due to thermally activated mechanisms that dominate material viscoplastic properties as the temperature was increased,

such as grain boundary sliding and recovery processes.^[18] Warm/hot forming involves dynamic microstructural changes,^[28–30] e.g., strain hardening, recovery, recrystallization, and grain evolution that occur during deformation, which are highly temperature dependent and deformation rate dependent.

A set of dislocation-based hardening constitutive equations, which interpret the unified viscoplastic behavior at warm/hot forming conditions, has been developed by Lin et al.^[31,32] The full set of the constitutive equations are listed below:

$$\dot{\epsilon}_p = \left(\frac{\sigma / (1 - \omega) - R - k}{K} \right)^\eta \quad (1)$$

$$\dot{R} = 0.5 B \bar{\rho}^{-0.5} \dot{\bar{\rho}} \quad (2)$$

$$\dot{\bar{\rho}} = A (1 - \bar{\rho}) \left| \dot{\epsilon}_p \right| - C \bar{\rho}^{\eta_2} \quad (3)$$

$$\dot{\omega} = \frac{\eta_1}{(1 - \omega)^{\eta_3}} \left(\left| \dot{\epsilon}_p \right|^{\eta_2} \right) \quad (4)$$

$$\sigma = E (1 - \omega) (\epsilon_T - \epsilon_p) \quad (5)$$

where ϵ_T and ϵ_p are the total and plastic strains, respectively. The isotropic hardening variable, R , is a function of the normalized dislocation density that is expressed as $\bar{\rho} = (\rho - \rho_i) / (\rho_m - \rho_i)$, where ρ is the actual dislocation density, ρ_i is the initial dislocation density in the virgin state, and ρ_m is the maximum (saturated) dislocation density that the material could have. The normalized dislocation density, which varies from 0 (the initial state) to 1 (the saturated state of a dislocation network), is the ratio between the newly generated dislocation density and the maximum dislocation density that can be generated by deformation. Detailed dislocation hardening evolution is described by Lin et al.^[28]

The damage evolution is represented by Eq. 4. Damage variable ω for the uniaxial formulation is strain rate dependent, which also influences viscoplastic flow (Eq. 1) and flow stress (Eq. 5). The damage value at the initial state of deformation is 0, while it reaches to 0.7 as failure of the material takes place. According to the features of the model, the strain increment in stress–strain curves, as the damage value rises from 0.7 to 1.0, is small and could be omitted. Computational efficiency could be significantly improved in finite element simulation^[18] using the simplified assumption. As deformation rate and temperature change with locations in the workpiece and time in the course of deformation, the dominant damage mechanism may vary throughout the HFQ® process. Thus, the model introduced above is to model overall damage effects, instead of a particular damage mechanism of a material under warm/hot forming conditions.

The parameters K , k , A , B , C , E , η_1 , η_2 , η_3 , and n are temperature-dependent material constants,^[9] where E is

Fig. 6 Comparison of computed (solid curves) and experimental (symbols) stress-strain relationships for AA5754 deformed at (a) different strain rates at a temperature of 250°C and (b) different deformation temperatures at a strain rate of 1/s

the Young's modulus of the material. Arrhenius equations are used to express the temperature constants as follows:

$$K = K_0 \exp\left(\frac{Q_K}{RT}\right) \quad (6)$$

$$k = k_0 \exp\left(\frac{Q_k}{RT}\right) \quad (7)$$

$$B = B_0 \exp\left(\frac{Q_B}{RT}\right) \quad (8)$$

$$C = C_0 \exp\left(-\frac{Q_C}{RT}\right) \quad (9)$$

$$E = E_0 \exp\left(\frac{Q_E}{RT}\right) \quad (10)$$

$$\eta_1 = \eta_{01} \exp\left(-\frac{Q_{\eta_1}}{RT}\right) \quad (11)$$

$$\eta_2 = \eta_{02} \exp\left(\frac{Q_{\eta_2}}{RT}\right) \quad (12)$$

$$\eta_3 = \eta_{03} \exp\left(-\frac{Q_{\eta_3}}{RT}\right) \quad (13)$$

$$A = A_0 \exp\left(-\frac{Q_A}{RT}\right) \quad (14)$$

$$n = n_0 \exp\left(\frac{Q_n}{RT}\right) \quad (15)$$

The equations were numerically integrated using the implicit Euler method with automatic step size control.^[9] Uniaxial tension test results obtained at different temperatures and strain rates were used to calibrate the above equations and to determine the materials constants.^[33] In the case of AA5754,^[12] there are 20 different material constants within the equation set that were determined by fitting the equations to the experimental data using

optimization techniques.^[34] The range of possible values for the constants was defined based on their physical meanings and from the experience. The constants are listed in Table 1. A comparison between the stress–strain behavior predicted by the material model and that obtained from the uniaxial tension tests is shown in Fig. 6.

Forming Limit Diagram

Forming limit diagram (FLD), also known as a forming limit curve (FLC), is used in sheet metal forming for determining the likely occurrence of failure, for given strain conditions. It represents the limit strains for different strain paths in the principal strain space and is widely used for formability simulation in metal forming process. The concept of FLD distinguishes between the major and minor strain combinations that are safe, and the ones that would lead to necking or failure. If a point lies above this curve, then localized necking occurs.^[35] Many researches have been concerned with the determination of forming limits both experimentally and theoretically, and various testing methods are used to obtain the experimental FLD using stretch-forming tests.^[36] Two of the most commonly used test methods are the Marciniak type test^[37] and Nakajima type test.^[38] Different geometries and widths of test piece have been used by different researchers, when using these tests, to produce different strain states, from uniaxial to plane strain, to equibiaxial tension. Normally the test pieces have either a parallel waisted section^[39] or strips^[40] or hourglass-shaped geometry,^[41] except the equibiaxial test pieces. In addition to the above mechanical stretching tests, a recent method called the pneumatic stretching test, in which gas is used for forming, has been successfully employed to determine high temperature forming limits for the magnesium alloy.^[42]

An example of an FLC is shown in Fig. 7a. The geometry of the test piece is that of a waisted circular blank with a waist of constant width, as shown in Fig. 7b. Although standards for high temperature formability tests do not exist yet, the ones set out in ISO 12004-2:2008^[43] were closely adhered to as a foundation for the kind of formability tests. The method for measuring strains on deformed test pieces is also described in the standard. The ratio of major to minor strain values in

Fig. 7 (a) Schematic drawing of the test points for a FLC and (b) specimens tested at room temperature at a punch speed of 5 mm/s^[44]

a test piece can be varied by altering the ratio of waist width to diameter of the test piece. Therefore, a set of tests, which uses the different geometries with various biaxial strain ratios, can be obtained to generate the FLC, as shown in Fig. 7.

Understanding the formability of a sheet material is essential for optimizing forming processes. This is particularly the case when they are applied to numerical simulations through the calibration of necking or failure prediction models, to predict whether a component can be formed successfully or not. In the HFQ® processes, the sheet metal is heated and the tool is relatively cool. During deformation, temperature and strain rate may vary dynamically in both time and location in the sheet metal. The ductility of aluminum alloys increases with temperature and is further enhanced by deforming at a lower speed. It is noted that it is not necessary to increase drawing depth at a low forming speed, even if the material ductility increases. This will enable the successful formation of complex-shaped aluminum sheet components.^[45]

Figure 8a shows the FLCs for different forming temperatures, at a forming speed of 75 mm/s, except for the room temperature tests which are insensitive to strain rate, for which a speed of 5 mm/s was used.

Fig. 8 FLCs obtained by formability tests at (a) different temperatures with a constant forming speed of 75 mm/s and (b) different forming speeds with a constant temperature of 250°C^[44]

Generally, formability increases with increasing temperature as evidenced by the shift up of the FLCs along the major strain axis. The increase is more pronounced at higher temperature. It is noticeable that there is little increase in forming limit between room temperature and 200°C. The increase in the formability from 250°C to 300°C is about twice of that from 200°C to 250°C in the plane strain region. These results suggest that the warm forming temperature should be in the region of 250°C–300°C. As temperature increases, the V-shape of the FLCs appears to become flat, which shows the reduced effects of the minor strain on the formability, although it is still obvious at 300°C.

The effect of forming speed on the FLCs is shown in Fig. 8b for the forming temperature of 250°C. The forming limit increases with decreasing forming speed, suggesting that the best ductility lies at low speeds for warm forming. The effect of decreasing speed is therefore similar to that of increasing temperature. From Fig. 8, it can be seen that when speed decreases from 300 to 75 mm/s, the forming limit increases in the plane strain region, and the FLC curve is flatter. A significant improvement in the forming limit is observed from 250°C to 300°C.

Considering typical cold forming rates that are expected by the industry, a compromise is needed for the selection of the most suitable forming speed. A high speed is conducive to a high production rate, but a low speed provides better formability. It should be mentioned that the effects of forming rate and temperature are interrelated. It is also concluded that using a combination of low forming rate and high forming temperature is beneficial for enhancing the forming limit in an isothermal forming environment, which is within the limit of the study.

Plane Stress Damage Constitutive Equations

In a manner similar to that for creep deformation,^[46] the general multiaxial power law viscoplastic equations can be obtained by consideration of a dissipation potential function. With an initial yield stress, k , and ignoring the work hardening and other state variables, an energy dissipation potential can be in the form of

$$\psi = \frac{K}{n+1} \left(\frac{\sigma_e - k}{K} \right)^{n+1} \quad (16)$$

where $\sigma_e = \left(3S_{ij}S_{ij}/2 \right)^{1/2}$ is effective stress, $S_{ij} = \sigma_{ij} - \delta_{ij}\sigma_{kk}/3$ is the deviatoric stress tensor, σ_{ij} is the stress tensor, and δ_{ij} is the Kronecker delta; K and n are material constants. Assuming normality and the associated flow rule, the multiaxial relationship is given by

$$\frac{d\epsilon_{ij}^p}{dt} = \frac{\partial \psi}{\partial S_{ij}} = \frac{3}{2} \left(\frac{S_{ij}}{\sigma_e} \right) \left(\frac{\sigma_e - k}{K} \right)^n \quad (17)$$

where ϵ_{ij}^p is the plastic strain tensor. By the introduction of isotropic hardening (R) and damage-state variables (ω), the effective plastic strain rate, $\dot{\epsilon}_e^p$, for the power law material model can be written as^[46]

$$\dot{\epsilon}_e^p = \left(\frac{\sigma_e / (1 - \omega) - R - k}{K} \right)^n \quad (18)$$

It is worth noting that Eq. 18 is tenable only when $\sigma_e / (1 - \omega) - (R + k) > 0$, otherwise $\dot{\epsilon}_e^p = 0$. The set of

multi-axial viscoplastic constitutive equations, incorporating multi-axial damage evolution, may be written as

$$\dot{\epsilon}_{ij}^p = \frac{3}{2} \frac{S_{ij}}{\sigma_e} \dot{\epsilon}_e^p \quad (19)$$

$$\dot{R} = 0.5 B \bar{\rho}^{-0.5} \dot{\bar{\rho}} \quad (20)$$

$$\dot{\bar{\rho}} = A(1 - \bar{\rho}) |\dot{\epsilon}_e^p| - C \bar{\rho}^{\eta_2} \quad (21)$$

$$\sigma_{ij} = (1 - \omega) D_{ijkl} (\epsilon_{ij} - \epsilon_{ij}^p) \quad (22)$$

$$\dot{\omega} = \frac{\Delta}{(\alpha_1 + \alpha_2 + \alpha_3)^\varphi} \left\langle \frac{\alpha_1 \sigma_1 + 3\alpha_2 \sigma_H + \alpha_3 \sigma_e}{\sigma_e} \right\rangle^\varphi \cdot \frac{\eta_1 \sigma_e}{(1 - \omega)^{\eta_2}} (\dot{\epsilon}_e^p)^{\eta_3} \quad (23)$$

where D_{ijkl} is the elastic matrix of the material. The multi-axial damage Eq. 23 comes from the uniaxial form with the consideration of the multi-axial stress state effect.^[47] The details are as follows:

- The α_1 , α_2 , and α_3 are weighing parameters that present the damage evolution and introduced to rationalize the effects of the stress states on damage evolution and turn on the shape of FLC. These parameters are mainly controlled by maximum principal stress, effective stress and/or hydrostatic stress and are defined according to experience. In conclusion, it was determined that α_1 and α_3 are varied from 0 to 1. However, α_2 is changed from -1 to 1 in which the effect of hydrostatic stress could be in negative direction. If α_1 or α_2 or α_3 is zero, then the particular stress has no contribution to the damage process of the material for sheet metal forming conditions.
- φ is a multi-axial stress damage exponent, which controls the effect of multi-axial stress values and their combination on damage evolution; thus, it controls the formability. Parameter φ controls the shape of the FLC.
- Δ is a correction factor representing the tensile data obtained from uniaxial tensile tests and Marciniak or Nakazima formability tests^[37,48] since different strain measurement methods are normally used.

The plane stress problem is defined to be a state of stress in a thin sheet in which the normal stress σ_3 (through the thickness of the sheet metal) is small and is assumed to be zero. The condition must be true on the free surface of a deforming sheet. The numerical procedure for solving the above equations for a plane stress situation and fitting experimental FLCs has been detailed in reference.^[49]

Unified Viscoplastic Hosford M–K Forming Limit Model

Sheet metal formability has been shown to be sensitive to temperature, strain rate, and strain path.^[50] However, due to the time and resources required to generate a single FLD, it would not be realistic to produce one for every possible condition that occurs in a forming process. In addition, the strain rate and temperature over the work-piece vary with time and location in a HFQ® forming process. As can be seen in Fig. 8, FLCs are based on constancy of temperature and strain ratio, and it is therefore impossible to use a single curve to assess the sheet formability. Experimentally determined FLCs would no longer be applicable to such a process due to the varying temperature, strain rate, and strain path at different regions of the sheet metal during the forming. In effect, each location of a formed component would have its own loading history, and theoretically, a unique FLD would be required for each location. A sensible forming limit prediction model is therefore essential.

The Marciniak and Kuczynski, or M–K model, is a strain localization model that assumes that sheet metals have preexisting imperfection zones with slightly lower thicknesses than the rest of the material.^[51] The model makes use of a nonhomogeneity coefficient, or imperfect factor, which accounts for the initial discrepancy in the thickness. Due to the thickness inhomogeneity, as the deformation progresses, a point will be reached where deformation in the thinner region, designated *zone B*, increases at a much faster rate than the surrounding material, or *zone A*, resulting in necking and subsequent failure. As the deformation progresses, the imperfect factor f (Eq. 24) decreases and strain is localized at *zone B*; failure occurs when the ratio of strains in *zones B* to *A* approaches a critical value, shown in Eq. 25:

$$f = \frac{t_B}{t_A} = f_0 \exp(\epsilon_{3B} - \epsilon_{3A}) \quad (24)$$

$$\frac{d\epsilon_{1B}}{d\epsilon_{1A}} \geq 10, \text{ or } \frac{d\epsilon_{3B}}{d\epsilon_{3A}} \geq 10 \quad (25)$$

where f_0 is the initial value of the imperfect factor, determined by calibrating against the FLCs obtained from the formability tests. It is noted that the imperfect factor, based on the M–K model, can be expressed as a function of temperature and strain rate.

The different points along the FLCs representing different strain conditions were calculated by varying the ratio between the minor and major strains in *zone A*. This ratio, denoted as β , has a value of -0.5 for the uniaxial condition, and a value of 1 in the biaxial condition. To determine the evolution of the strains in *zone B*, it is assumed that the strains are compatible at the interface between *zones*

A and B where the minor strains are equal to each other, and there is mechanical equilibrium along the interface.

$$\varepsilon_{2A} = \varepsilon_{2B} \quad (26)$$

$$\sigma_{1A} = f\sigma_{1B} \quad (27)$$

All the following equations had to be solved simultaneously for both *zones* A and B. The viscoplastic flow rule is shown in Eq. 28, and is a function of the flow stress and the isotropic hardening variable R (Eq. 29). This in itself is a function of the normalized dislocation density (Eq. 30), which accounts for the accumulation and annihilation of dislocations during deformation; hence, R captures the effect of hardening due to dislocation pileup and entanglement.^[31]

$$\dot{\bar{\varepsilon}}_{p(A,B)} = \left(\frac{\bar{\sigma}_{(A,B)} - R_{(A,B)} - k}{K} \right)^{n_1} \quad (28)$$

$$R_{(A,B)} = B\bar{\rho}_{(A,B)}^{-0.5} \quad (29)$$

$$\dot{\bar{\rho}}_{(A,B)} = A(1 - \bar{\rho}_{(A,B)})\dot{\bar{\varepsilon}}_{p(A,B)} - C\bar{\rho}_{(A,B)}^2 \quad (30)$$

$$\bar{\sigma}_{(A,B)} = E \left(\bar{\varepsilon}_{(A,B)} - \bar{\varepsilon}_{p(A,B)} \right) \quad (31)$$

where k , K , n_1 , B (Eq. 29), A (Eq. 30), n_2 , and E are temperature-dependent material constants calibrated using the results of uniaxial tension tests. The suffixes (A, B) represent the corresponding variables in *zone* A and *zone* B. The equations are solved until one of the failure conditions is satisfied. The minor and major strains in *zone* A at failure are hence the limit strains for that particular β value; by combining the limit strains for each β value, a FLD for a constant temperature, strain rate, and strain path can be constructed. The use of a time integration procedure also enables the effect on the FLD of time-dependent phenomena and process conditions, such as the varying temperatures, strain rates, and strain paths in a hot stamping process, to be captured.

Anisotropic Yield Function

In order to obtain an accurate prediction of the incidence of localized necking in sheet materials, it is crucial that an anisotropic yield function is incorporated in the model. In particular, da Rocha et al.^[52] stated that while the sheet thickness does not have an effect on the forming limits, for thinner sheets, it is the additional rolling that affects the mechanical properties, leading to increased anisotropy and different flow behavior, which must be captured by the developed models.

Numerous yield functions have been developed over the past decades for modeling the anisotropic sheet metals,

including the Hill,^[53] Hosford,^[54] and Barlat^[55] yield functions. For the HFQ® forming processes, the anisotropic nature of sheet material is represented by the Hosford yield function,^[54] shown in Eq. 32.

$$R_2\sigma_{1(A,B)}^a + R_1\sigma_{2(A,B)}^a + R_1R_2\left(\sigma_{1(A,B)} - \sigma_{2(A,B)}\right)^a = R_2(R_1 + 1)\bar{\sigma}_{(A,B)}^a \quad (32)$$

where R_1 and R_2 are the strain ratios (r -values) in the longitudinal and transverse, respectively, determined from the uniaxial tension tests. The constant a , which is set to 6 for AA5754, depends on the crystallographic structure of the material.

To calculate the components of stress, an additional variable ϕ is first introduced, which is the ratio of the major stress to the equivalent stress.

$$\phi_{(A,B)} = \sigma_{1(A,B)} / \bar{\sigma}_{(A,B)} \quad (33)$$

The Hosford yield function is then modified in such a way that it is expressed in terms of the variables, ϕ and α . Hence, with the calculated value of the principal stress ratio and the value of the equivalent stress output from the viscoplastic equations, the major stress is determined.

$$\phi_{(A,B)} = \frac{1}{\left(\frac{1}{R_2(R_1 + 1)} \right)^{1/a} \left[R_2 + R_1\alpha_{(A,B)}^a + R_1R_2(1 - \alpha_{(A,B)})^a \right]^{1/a}} \quad (34)$$

By assuming the plane stress conditions, the stress in the thickness direction is set to zero and the minor stress can be calculated. Thus, all the strain and stress components in *zone* A are determined using these equations, and the defining relations of the M–K model, Eqs. 24–27, can be used to obtain the strains and stresses in *zone* B. A major advantage of this method is that the effect of time-dependent phenomena and process conditions on the FLD, such as the varying temperatures, strain rates, and strain paths encountered in a hot stamping process, can be captured, due to the use of a time integration procedure.

With the material model for AA5754 calibrated and verified using the results of the uniaxial tension tests, it is then applied in the prediction of forming limits for the material. Figure 9a shows close agreements between the predicted and experimental FLDs at temperatures between 200°C and 300°C, at a forming speed of 75 mm/s. It is believed that the pronounced strain rate hardening effect at higher temperatures leads to increased formability. In particular, the higher strain rate in *zone* B will increase the strength difference between *zones* A and B, gradually limiting the strain ratios between them and therefore delaying the onset of necking at *zone* B. The effect of a quenching rate of 50°C/s being applied from an initial temperature

of 300°C is also presented. The resulting FLD is lower as expected, indicating a drop in the formability as a result of temperature decreasing.

Figure 9b shows good agreements between the predicted and experimental FLDs at forming speeds of 20 and 300 mm/s at a temperature of 250°C. Both strain hardening and strain rate hardening enhance formability. Strain hardening is more pronounced at low-temperature conditions, while the strain rate hardening is the dominant factor at higher temperatures. Hence at the onset of strain

localization in *zone B*, and the resulting steep increase in strain rate, the strength in this region is increased, eventually delaying the onset of necking; at 250°C, the formability is therefore higher when the strain rate is lower. The effect of a strain rate reduction to 0.25/s applied from an initial strain rate of 3.5/s is also presented; as expected, the resulting FLD is higher, indicating an improvement in the formability as a result of strain rate decreasing.

A change in strain path on the FLD of AA5754 is also successfully captured, as shown in Fig. 10. Uniaxial

Fig. 9 Predicted and experimental FLDs at (a) different temperatures with a speed of 75 mm/s and (b) different forming speeds with a temperature of 250°C^[56]

Fig. 10 Effect of change in strain path on the FLD, at the temperature of 300°C and the average strain rate of 0.88/s^[56]

pre-stretching enhances the formability of the material during biaxial straining, while biaxial pre-stretching enhances the formability of the material during uniaxial straining. This is consistent with many previous research findings, such as those of Graf and Hosford.^[57,58]

HFQ® APPLICATIONS

Aircraft Wing Stiffener

The wing stiffener component was previously produced using resource intensive machining and thus demonstrated many advantages of the HFQ® process over the existing processes. A die set, as shown in Fig. 11, was designed to investigate the formability of aluminum alloys under anisothermal hot stamping conditions.^[12] The tool was mounted onto a 250 kN ESH press, which provided the forming load. The workpiece was first heated in a furnace to the target temperature and then monitored using a thermocouple wire attached to it. It was quickly and carefully

placed in the tool within 10 s to stamp the workpiece when the press was activated.

As the load was applied, the top blank holder was displaced downward, compressing the 1st stage blank holding force (BHF) springs. With the workpiece held between the top and bottom blank holders, the top die deformed the blank further toward the bottom die, engaging the 2nd stage BHF gas springs. The formed part was then held in the cold die to quench it to room temperature. Subsequently, the load was removed and the ejector springs separated the blank holders, enabling removal of the part. The die, blank holders, and punches of the tool were lubricated before each test using lubricating oil.

Rectangular sheets of AA5754 with dimensions of $200 \times 65 \times 1.5 \text{ mm}^3$ were used to form the wing stiffener components under the HFQ® temperature of 480°C . The finite element (FE) model developed in ABAQUS was verified by comparing the numerical results with the experimental results.^[12] As can be seen from Fig. 12a, in which the part was formed at a temperature and speed of 480°C and 250 mm/s, the simulated part in Fig. 12b was geometrically

Fig. 11 (a) Geometric model and (b) photograph of the stamping tool used^[12]

Fig. 12 (a) Successfully formed AA5754 part, and (b) simulated part with plastic strain contour displayed^[12]

accurate, exhibiting a near perfect match with the experimentally formed part. Figure 12b also shows that the highest plastic strains occurred at the corner regions of the part, with the maximum value being approximately 78%, where localized thinning took place.

Numerous trials were conducted on large blanks as well as strips of different materials to demonstrate the feasibility of forming them using HFQ® and to analyze the detailed aspects of the process.^[12,13,22] For heat-treatable high-strength aluminum alloy series, such as AA2xxx, AA6xxx, and AA7xxx, the HFQ® process was found to successfully enable the forming of the sharp corners and complex central features, compared to the complete failure observed from cold forming. Significant savings in materials and costs are also possible when using HFQ® instead of machining with negligible material wastage and a reduced cycle time. A selection of formed wing stiffener components made from different aluminum and magnesium alloys using the HFQ® process is shown in Fig. 13.

Vehicle Bulkhead

The trials of forming the bulk head were carried out based on the optimization of process parameters (temperature, time, friction (lubricant), and BHF) to achieve the successful formed parts. The bulkhead component further

established the potential of HFQ® through extensive laboratory experiments. The aluminum alloys AA6082 and AA5754 have been used in the trials, and both successfully formed into the components using HFQ®, as shown in Fig. 14.

The large draw depth of the component means that it cannot be formed using the conventional cold or warm forming due to the insufficient formability of both alloys at low temperatures. However, forming the component at HFQ® conditions without any localized thinning and cracks still required careful optimization of the forming parameters, including the forming speed and the initial blank shape. It was found that higher forming speeds were beneficial for the process as the strain rate hardening effect was enhanced and temperature homogeneity was improved, due to the reduced available time for heat transfer between the hot blank and the cold tools.^[11] Consequently, the components were formed with no observable necking.

Vehicle Rear Floor Panel

The rear floor panel is the first full scale automotive component that is produced using the HFQ® process. The component, shown in Fig. 15, has outer dimensions of approximately 875×125 mm, with a draw depth of 52 mm, and was produced from a 1.5 mm thick sheet material.

Fig. 14 Vehicle bulkhead component formed from (a) AA6082 and (b) AA5754. Design and forming tool were supplied by Lotus Cars, UK

Fig. 15 Vehicle floor enforcement component formed from AA7075 using the following: (a) cold and (b) HFQ® forming processes. Design and forming tool were supplied by Centre Research of Fiat (CRF), Italy

Cold forming could not be used to form the component from the aluminum alloys AA6082 and AA7075, whereas the use of the HFQ® process repeatedly produced successful components. The capability of the process was particularly highlighted by the forming of AA7075, which is a very high-strength alloy with limited formability that has been gaining interest in the automotive industry. A comparison between the cold formed and HFQ® formed AA7075 sheet for this floor component is seen in Fig. 15.

Vehicle Door Inner Panel

The structural parts that are made out of HFQ® high-strength aluminum become competitive candidates to reduce the weight of future vehicles, trains, and airplanes. The first-ever car door inner that was made from high-strength aluminum by the HFQ® at AP&T^[59] is shown in Fig. 16.

The use of a shape-optimized blank not only saves material but also helps reduce the presence of defects, e.g., necking, cracking, and wrinkling during the forming of the complex-shaped parts. The initial blank shape usually affects the material flow significantly during forming, and hence, a sensible design of the blank shape is critical to the success of the hot stamping process and quality of the final products.

The door inner is the largest and most complex component formed by the HFQ® process, and had only previously been produced successfully through the cold forming of AA5754. Using the HFQ® process, the high-strength AA6082 sheet was successfully formed into the required shape, as shown in Fig. 16. To reduce the efforts of trial-and-error experiments, advanced finite element simulation has been used to determine the optimal blank geometry and optimize the forming design.^[60]

Other Vehicle Structural Components

The high-strength aluminum alloys present special challenges for the forming process with regard to formability. Using the cold forming, only geometrically simple parts can be produced from these alloys. A strong relationship has been established between Imperial College and the world leading press manufacturers,

Fig. 16 The first HFQ® formed high-strength aluminum (AA6082) vehicle door inner panel in the world. Design and forming tool were provided by Lotus Cars, UK

Fig. 17 HFQ® formed high-strength aluminum (AA7075) vehicle components

AP&T and Schuler. The HFQ® of sheet metals for mass production are developed in the companies, and a wide variety of aluminum alloys have been already processed by the technology. With the aid of specially designed forming dies, it is now able to demonstrate the potential of HFQ® technology by producing a range of reference parts, as shown in Fig. 17. The combination of temperature control and forming technology to achieve the desired characteristics of part is of crucial importance here.

HFQ® Tailor Welded Blanks

Tailor welded blanks (TWBs) that consist of multiple sheet materials joined with welds have been widely used in the lightweight structures. The market for aluminum alloys is expanding into various sectors, most significantly in the automotive industries where the use of TWBs in aluminum is developing rapidly.^[61]

The HFQ® process has been introduced into the forming of laser-welded AA6082 TWBs,^[19] as shown in Fig. 18. The

Fig. 18 HFQ® formed AA6082 parts: (a) 2–1 mm TWB, (b) 2–1.5 mm TWB, and (c) 1.5–1.5 mm TWB

degraded mechanical properties of the TWB can be restored after the HFQ® forming and artificial aging, which highlights the advantages of the HFQ® process.^[62] AA6082 TWBs with different thickness combinations of 2–1, 2–1.5, and 1.5–1.5 mm have been investigated to reveal the TWB thickness ratio effects on the forming behavior. The HFQ® formed TWBs exhibited different failure modes: localized necking parallel to the weld line for the 2–1 mm TWB, circumferential necking for the 1.5–1.5 mm TWB, and a mixture of the parallel and circumferential necking for the 2–1.5 mm TWB. Thickness ratio has an important effect on the extent of the weld line movement, and it was found that the weld line shift increases as the thickness ratio is increased.

CONCLUSIONS

The need for lightweight metal alloys, and advanced forming technologies to produce high-strength components, will continue to rise as the vehicle fuel efficiency requirements become ever more stringent. The SHT, forming, and in-die quenching, or HFQ®, is a novel hybrid forming process that is developed to enable the production of complex-shaped lightweight structures for ever-growing applications. The HFQ® does not require specialized alloy grades. It can form parts at least as fast as the cold forming and operate to the extent that the aluminum has significantly extended ductility. There have been many applications of the process since its inception, both in the laboratory and at the industrial scale, where components with highly complex geometries have been produced, with a high postform strength potential.

The HFQ® combines both forming and heat treatment in a single process whereby upon heating the sheet metal, it is stamped and held between cold tools to quench the component to room temperature. The strain rate and temperature over the workpiece therefore vary with time and location throughout the deformation. Advanced finite element simulation integrating the unified viscoplastic material model is able to represent the thermomechanical behavior of the material. From the formability test results, it is concluded that, within a specified range, using a combination of low forming speed and high forming temperature is beneficial for

enhancing the forming limit in an isothermal forming environment. However, this is not the case in an anisothermal condition, such as the HFQ®. A forming limit prediction model, also known as the Hosford M–K model, has been presented and successfully validated using the formability tests on various aluminum alloys, e.g., AA2024, AA5754, AA6082, and AA7075. The ability of the model to capture the time-dependent phenomena is also demonstrated, with obvious effects on the material's formability as a result of the changes in temperature, strain rate, or strain path.

Hot Tear Nucleation During Solidification of Aluminum and Its Alloys

Murat Tiryakioğlu and Pedram Yousefian

School of Engineering, University of North Florida, 1 UNF Drive, Jacksonville, Florida, 32224, United States

Abstract

This article presents a discussion of hot tear formation by first re-interpreting tensile test experimental results for aluminum castings in the literature. Based on the previous findings that a pore should first nucleate to result in a hot tear, the physics of pore formation is reviewed through theoretical fracture pressure calculations. Theoretical fracture pressure of liquid aluminum was calculated to be approximately -3.5 GPa, which is 4 orders of magnitude higher than the tensile strength data reported in the literature. Further calculations showed that it was impossible for a pore to nucleate either homogeneously or heterogeneously in liquid aluminum. The formation of pores and hot tears in aluminum castings can only be explained by inflation of entrained surface oxide films (bifilms) under reduced pressure and/or with dissolved gas, which involves only growth, avoiding any nucleation problem. This mechanism is consistent with tensile test results in the literature as well as physics principles.

Keywords: Bifilms; Casting; Fracture pressure; Hot tearing; Liquid fracture; Porosity.

INTRODUCTION

Hot tear is the formation of a crack on the surface of a casting during solidification, visible to naked eye. Hot tears and pores are among the most serious casting process defects that lead to the rejection of the casting, resulting in higher production costs. The two defects are quite different in appearance and location. Yet nucleation of a pore under tensile stress (uniaxial and hydrostatic for hot tears and pores, respectively) is the first necessary step in both defects. *In situ* observations of transparent liquids have confirmed^[1] the necessity of this first step.

To understand hot tear tendencies, there have been several studies to determine the mechanical properties of pure metals and alloys in a semisolid state. In these studies, specimens should retain their initial shape to withstand the tensile in a semisolid state. Mechanical testing has been performed in two ways: by heating the sample to a certain temperature above the solidus (remelting) or by cooling the liquid alloy to a certain temperature below the liquidus (solidification). The results of mechanical tests are different due to the obtained structure difference.^[2]

It is usually assumed that the metal in the semisolid or even the liquid state is not capable of withstanding tensile stresses. However, these assumptions, although verified by experimental data, are not necessarily based on physics. The differences between experimental results in the literature and the physics of pore nucleation are addressed,

and a mechanism that bridges the gap between physics and experimental results is discussed.

A REVIEW OF TENSILE TEST RESULTS NEAR MELTING TEMPERATURE

Fredriksson et al.^[3] conducted an experiment to investigate the tensile properties of pure aluminum as a function of temperature approaching the melting temperature of 660°C . Their results are presented in Fig. 1. Note that fracture pressure goes down to about 2.5 MPa at 640°C when the metal is completely solid, after which there is a sudden drop to about ~ 0.1 MPa level as the temperature approaches 660°C . The results of Fredriksson et al. are consistent with those reported in the literature for aluminum and its alloys, which are summarized in Table 1.

The results presented in Table 1 clearly show that aluminum and its alloys lose their strength significantly as the metal is heated up to its melting temperature, where strength drops to essentially zero and therefore cannot withstand the tensile stresses developed during solidification. Hence, it has been assumed in foundry practice and alloy development projects that hot tears are driven by metallurgical factors such as chemical composition. For this reason, wrought aluminum alloys and Al-Cu alloys have been considered to be “very difficult to cast.” Although chemical composition does affect the thermal stresses

Fig. 1 Experimental results of Fredriksson et al.^[3] for fracture stress of pure Al for 0.1 K/s cooling rate

generated during solidification, stresses provide the driving force for crack growth, whereas there are other factors that need to be considered for the nucleation of a hot tear. However, nucleation has not received as much attention in hot tear literature. This article is motivated to fill this gap.

CAVITATION AND HOT TEAR NUCLEATION

Eskin and Katgerman^[20] summarized the mechanisms of nucleation of hot tears suggested in the literature. These mechanisms are as follows:

Liquid film or pore as stress concentrator

Vacancy clusters at a grain boundary or solid/liquid interface

Oxide bifilms entrained in the mush

The first two mechanisms can be combined together; vacancy clusters are expected to form due to ordering of atoms during transition from a liquid to a solid state. The combination of vacancy clusters and tensile stresses generated during solidification can jointly lead to the nucleation of a pore that will grow as a crack and propagate to form the hot tear. To evaluate this possible interaction, nucleation theory and its application to pore formation will be reviewed. For more details, the reader is referred to the authors' previous publications.^[21,22]

Let us consider a pore nucleus with the external pressure, P_e , acting outside its surface and the internal pressure, P_g , filling the pore with dissolved gas. Then the total work for the formation of the pore is:

$$W = \sigma A + V(P_e - P_g) \quad (1)$$

Assuming that pore nucleus is spherical and denoting $(P_e - P_g)$ as ΔP , we have:

$$W = 4\pi r^2 \sigma + \frac{4}{3}\pi r^3 \Delta P \quad (2)$$

Note that the critical radius above which a pore is stable, r^* , is found by

$$r^* = \frac{-2\sigma}{\Delta P^*} \quad (3)$$

where ΔP^* is a negative number. The critical pressure, ΔP^* , has to reach the fracture pressure of the liquid, P_f , for a pore to form. If a liquid is brought suddenly into a metastable state, by nucleation and growth processes, pores may appear spontaneously and a phase separation takes place. The nucleation rate is then considered to be the product of the concentration of critical nuclei and the frequency with which they grow by addition of one molecule. Fisher^[23,24] stated that the rate of formation of bubbles of vapor in a mole of liquid subjected to a negative pressure P_f could be expressed as

$$J = \frac{N_A kT}{h} \exp \left[\frac{-(\Delta G_0^* + W^*)}{kT} \right] \quad (4)$$

Fisher^[23,24] asserted that the ΔG_0^* energy is related to the activation energy for viscosity, and the effect of viscosity of the liquid and the observation time is negligible on fracture strength, so assuming $t = 1$ s and $\Delta G_0^* = 0$ in all cases, it will not cause any significant error:

$$P_f = - \sqrt{\frac{16\pi\sigma^3}{3kT \ln \left(\frac{kN_A T}{h} \right)}} \quad (5)$$

Bankoff^[25] modified Fisher's equation by considering a superheated liquid:

$$P_f = - \frac{\rho_l}{\rho_l - \rho_g} \sqrt{\frac{16\pi\sigma^3}{3kT \ln \left(\frac{6kN_A^{2/3} T}{h} \right)}} \quad (6)$$

Both Fisher and Bankoff equations have been shown to be accurate for a number of liquids at room temperature such as water, benzene, and ethyl alcohol. Also molecular dynamics (MD) simulations validate the accuracy of these equations for liquid lead.^[26,27]

Taking the surface energy of liquid aluminum at melting temperature as 0.914 J/m²,^[28] fracture pressure for homogeneous pore nucleation in pure aluminum at melting temperature is calculated as −3.41 and −3.81 GPa by using the Fisher and Bankoff equations, respectively. These values are amazingly similar to ∼−3.50 GPa found in MD simulations of liquid aluminum^[29] and experiments with thin films of liquid aluminum.^[30] Therefore, the theoretical strength calculations of liquid aluminum are approximately 4 orders of magnitude higher than those reported in experiments outlined in Table 1. This difference is very significant and will be addressed later in the article.

It is also noteworthy in Fig. 1 that the tensile strength (or fracture pressure) of solid aluminum just below the melting temperature is ∼2 MPa. Martynyuk^[31] used the modified van der Waals equation to calculate the ideal tensile strength of metals in the solid state at melting temperature. Martynyuk found the ideal tensile strength of aluminum at melting temperature to be 4.80 GPa. Hence, there is a significant discrepancy between the theoretical values and experimental results for both liquid and solid states at the melting temperature.

Turning our attention to Eq. 3, the critical radius for homogeneous nucleation of a pore, r^* , is calculated as 0.535 and 0.478 nm for the Fisher and Bankoff equations, respectively. In the absence of dissolved gas, the only mechanism available for a pore to nucleate is the formation of a vacancy cluster with a radius equal to r^* , because of the supersaturation of vacancies created during the

solidification process.^[3,32] The number of vacancies in the cluster with the critical pore size, n^* , is found by:

$$n_v^* = C_{AP} \left(\frac{r^*}{r_A} \right)^3 \quad (7)$$

C_{AP} is 0.74 for aluminum because of its face-centered cubic crystal structure. The number of vacancies in the cluster with the critical pore size was calculated by inserting r^* in Eq. 7. The number of vacancies needed in a vacancy cluster to form a pore with the critical size calculated for the Fisher and Bankoff equations is 39 and 28, respectively. The results show that large vacancy clusters are needed for fracture, i.e., the initial pore formation. The probability of the formation of vacancy clusters of these sizes is addressed next.

Brooks^[33] derived an equation for the concentration, i.e., probability of vacancy clusters with n_v vacancies, $F(n_v)$, as follows:

$$F n_v = \left[c_v \exp \left(\frac{E_v - (E_n / n_v)}{kT} \right) \right]^{n_v} \quad (8)$$

Jackson^[34] calculated the formation energy of a vacancy (E_v) and spherical cluster of vacancy (E_n) as:

$$E_v = 12\sqrt{2}r_v^2\sigma \quad (9)$$

$$E_n = 15.36n^{2/3}r_v^2\sigma \quad (10)$$

Thomas and Willens^[35–37] conducted experiments to determine the vacancy concentration in liquid high-purity aluminum (99.996% Al) by quenching from the liquid state. In these experiments, vacancies formed dislocation loops instead of voids, similar to the results of Kuhlmann-Wilsdorf and Wilsdorf.^[38] The change in vacancy concentration (c_v) in aluminum in liquid and solid states with temperature is presented in Fig. 2. At the melting point of aluminum, the equilibrium vacancy concentration is $\sim 10^{-3}$, which has been used as an approximation for all metals.^[3]

By taking the radius of a vacancy in aluminum as 0.158 nm,^[39] and the equilibrium vacancy concentration at melting temperature as 10^{-3} , the probability of a vacancy cluster with the size of a critical pore was calculated for the three fracture pressure equations by using Eqs. 8–10. The probability of a vacancy cluster of 39 is 2.3×10^{-115} and of 28 is 3.6×10^{-94} . These results are extremely low probabilities, which confirms that homogeneous nucleation of pores in pure aluminum is not possible. The authors^[21,22] have recently reported that even by considering the effect of dissolved gas and curvature energy, homogeneous and heterogeneous nucleation of a pore in liquid aluminum is still impossible. If pores cannot nucleate in liquid aluminum either homogeneously or heterogeneously, (i) how can

Fig. 2 Relationship between vacancy concentration and temperature^[37] (Work done for US Government, no copyright.)

hot tears in aluminum castings be explained and (ii) why is the tensile strength of aluminum at high temperatures both in solid and liquid states so low?

RECONCILIATION OF EXPERIMENTAL RESULTS AND THEORETICAL CALCULATIONS

Although pores cannot nucleate in liquid aluminum, there is a mechanism by which pores can form and grow without nucleation. Campbell^[40–42] stated that surface oxides, when entrained, form double parallel oxide films (bifilms), which may open up by pressure of dissolved gas and/or negative pressure developed due to solidification shrinkage. Oxides found on the walls of pores^[21,43–46] in aluminum

castings support this point. Bifilms act as initiation sites for pores and hot tears. In the presence of bifilms, nucleation is completely bypassed because fracture of the liquid under pressure is no longer needed due to the crack-like nature of bifilms. To the authors' knowledge, this effect of bifilms, i.e., bypassing nucleation in pore formation, has not been highlighted previously. This point is supported by the findings of Fox and Campbell^[47] who conducted an experiment in which a reduced pressure test sample was observed via real-time X-ray radiography under different pressure levels. Two radiographs taken at pressures of 1.0 and 0.01 atm during this experiment are presented in Fig. 3. At 1.0 atm, there are no visible pores; however, there are numerous dark patches. When pressure is reduced, the dark patches, which are bifilms in their compact, convoluted state, open up under the expansion of entrained air (residual gases, hydrogen and argon) between the two layers of the oxide. Hence pores form without any nucleation, and only through growth (unfurling) of the bifilms, at only modest reduced pressures of almost 1 atm (or 0.1 MPa), consistent with the experimental tensile strength levels presented in Table 1. Note that this mechanism is (i) the third one listed by Eskin and Katgerman,^[20] and (ii) the only mechanism that can result in a crack during solidification after eliminating the possibility of the first two. However, although bifilms are necessary to form a hot tear, their effect should not be defined as nucleation.

The finding that hot tears in aluminum components are impossible without bifilms is consistent with the observations of Durrans and Hunt^[48] who conducted an experiment to study the solidification of a transparent analog of a metal by a transparent cell on a microscope slide (as described by Campbell^[40]). The cell was designed to have sharp corners around which the solidifying material could be stretched by the turning of a screw. Interestingly,

Fig. 3 Radiographs of reduced pressure test samples of the same as-melted Al-7Si-0.4 Mg alloy solidified under (a) a pressure of 1 atm and (b) a pressure of 0.01 atm^[47] (Courtesy of Prof. John Campbell)

it was not possible to start a hot tear in clean material, regardless of how much it was stretched against the corner. With increasing strain, the freezing mixture continued to stretch indefinitely with the dendrites rearranging themselves to accommodate the strain. When a small inclusion or bubble arrived near the corner, then a tear opened up immediately. In the absence of a pore or inclusion, a hot tear did not occur no matter how much strain was applied. These results are consistent with those reported by Chadwick and Campbell^[49] who investigated the hot tearing formation by pouring A201 alloy into a ring mold containing a central steel core. When the metal filled the mold without entraining surface oxides, no rings exhibited hot tears. These results point to the significant effect of bifilms in hot tear formation: when aluminum is free from bifilms, hot tears are impossible and the liquid metal can accommodate large stresses, up to ~3.5 GPa. When bifilms are present, hot tears form easily because the liquid metal fails at 0.1 MPa.

CONCLUSIONS

- Theoretical calculations showed that liquid aluminum can withstand stresses up to 3.5 GPa before fracture. This value is 4 orders of magnitude larger than those reported in the literature.
- A pore should be present in the solidifying metal to initiate a hot tear. The only mechanism available for pore formation in solidifying aluminum is the presence of bifilms, which can inflate due to reduced pressure and/or hydrogen segregation. Therefore, pore formation and hot tear do not involve nucleation; it is a pure growth process.
- Bifilms open up at a pressure difference as low as 1 atm (0.1 MPa), which corresponds to the majority of tensile test results for liquid aluminum in the literature.

Abstract

A careful technique of dissolution of the Al-rich phase is conducted in hypoeutectic Al–Fe alloys samples, which were solidified under a wide range of cooling rates envisaging deeper investigations on the skeletal arrangement of either Al_6Fe intermetallic fibers or Al_3Fe plates, and their dependence on solidification thermal parameters. The experiments were carried out with hypoeutectic Al–Fe alloys, subjected to equilibrium solidification from the melt, steady-state solidification (Bridgman growth), transient directional solidification in water-cooled and air-cooled molds and rapid solidification (laser remelting), thus permitting a significant range of microstructural scales to be examined. It is shown that Al_6Fe prevails for cooling rates >1.5 K/s, and that a short zone of coexistence of Al_3Fe and Al_6Fe phases exists for cooling rates <1.5 K/s, which is rapidly replaced with the prevalence of Al_3Fe intermetallics with further decrease in cooling rate. In contrast, even with high values of cooling rate, typical of the laser remelting process, the Al– Al_3Fe eutectic is shown to prevail.

Keywords: Al–Fe alloys; Dissolution technique; Intermetallics; Microstructure; Solidification.

INTRODUCTION

The properties of an alloy such as mechanical, corrosion, and wear resistances are directly related to the characteristics of its macro- and microstructural components. In terms of macrostructure, the size and the morphology of the grains typified by columnar or equiaxed morphologies have been extensively studied in the literature.^[1–3] More recently, in terms of microstructure, the analyses have been advancing inside the limits of the grain boundary, i.e., also focusing on the morphology, size, and distribution of microconstituents in cellular or dendrite networks of continuously varying solute content, secondary phases, and eventually porosity and inclusions. The secondary phases are normally intermetallic (IMC) particles dispersed around the dendrites or cell boundaries and have been receiving special attention. This is because the *in situ* properties of these intermetallics differ strongly from those characterizing the α -Al matrix. The volume fraction,

shape, and scale of IMC phases are functions of the alloy chemistry, solidification conditions, and heat treatment. From the liquid state, the cooling rate ($\dot{T}$) extent imposed during solidification dictates the nature and the distribution of the IMC compounds. The present study links two types of IMC compounds (Al_3Fe and Al_6Fe) to a wide range of $\dot{T}$ connected to solidification experiments performed with hypoeutectic Al–Fe alloys. Additionally, characterization of these intermetallics through conventional metallographic techniques is compared with a method of separation of IMC compounds using a technique of dissolution of the Al-rich phase. This article is organized into three main sections. An overview of Al–Fe alloys, their applications, and the way microstructural features affect the alloys properties are presented in the “Aluminum–iron Alloys” section. The “Experimental Procedure” section describes the solidification experimental methodologies used, which are associated with different ranges of cooling rates in different sections as follows: (I) equilibrium

solidification, (2) steady-state solidification: Bridgman growth, (3) transient directional solidification, and (4) rapid solidification: Laser remelting, whereas section “Classic Metallography and Dissolution Techniques” provides details of the used classic metallography and dissolution techniques. Finally, in the “Results and Discussion” section, the results from the characterization of as-solidified samples are discussed, supported by images obtained from two metallographic techniques: chemical compositions from an energy-dispersive X-ray (EDX) analysis system and X-ray diffraction patterns.

ALUMINUM-IRON ALLOYS

A number of applications may require Al-Fe based alloys as a basic material. For instance, manufacturing processes such as packaging, architectural sheet, and lithography sheet may be cited.^[4] One of the main commercial Al alloy series is AA 6xxx. This kind of alloy may form some Fe intermetallics, such as Al-Fe, Al-Fe-Si, and Al-Fe-Mn-Si phases. During casting, these phases are mainly found between the aluminum dendrites or cells. The cooling rate and the Fe to Si ratio decisively control the type of intermetallics to be attained during alloy solidification.^[5] Size, morphology, and distribution of IMC particles play a decisive role in the final performance of the metallic alloys, which means that such phases may affect mechanical strength,^[6–13] and corrosion resistance,^[14–22] among other properties.

Al-Fe alloys are of considerable commercial interest, partly because iron is almost invariably present at significant levels (0.2–1.0 wt%). Iron is added intentionally in some alloys to increase the high temperature strength.^[23–24] Under equilibrium solidification conditions, any iron in excess of its solid solubility limit (0.04 wt%Fe) forms a eutectic constituted by an Al-rich primary phase and IMC Al_3Fe particles. However, during nonequilibrium solidification, typical of DC castings, considerably different cooling rates exist at the casting surface and at the center, causing eventually the formation of metastable Al_mFe and Al_6Fe IMC phases in addition to the stable Al_3Fe phase.^[25]

In general, subsequent thermomechanical processing takes place after the casting stage. Four processing stages may affect the microstructure and application properties differently: as-cast, heat treated after casting, mechanically worked after casting, and worked and heat treated. The secondary phases (constituents, precipitates, and dispersoids) may be modified along the adopted processing route, especially considering their morphology and chemical composition.^[26,27] Mondolfo^[25] stated that the formability of Al-Fe alloys depends mainly on the size and distribution of intermetallics, since coarse Al_3Fe eutectic fibers tend to crack, inducing notches that reduce formability and fatigue resistance. On the other hand, finely

dispersed Al_6Fe eutectic fibers do not have similar effects. Keong and collaborators^[28] found that alloys with Al_6Fe IMC particles embedded into an Al-rich matrix present higher mechanical strength than Al_3Fe -based alloys, despite the lower ductility level. Furthermore, Kuijpers and coauthors^[5] reported that the unstable platelike Al_5FeSi phase, commonly present in the DC-casting extrusion alloys, negatively influences the extrusion properties of the alloy. The homogenization heat treatment will transform this phase into a less Si-rich and more spheroidised phase, favoring extrusion. Moreover, this transformation leads to a decrease in pickup defects on the extruded surface.

Some studies have reported a competitive growth between the IMC phases of Al-Fe alloys occurring during solidification, with the proportion of phases being determined as a function of solidification velocity. Allen et al.^[25] observed the coexistence of Al_3Fe and Al_6Fe over the solidification velocity range of 0.2–0.6 mm/s, which was shown to be independent of Fe alloying content, considering Al-0.5–1.5 wt%Fe alloys. For velocities higher than 0.6 mm/s, only Al_6Fe IMC particles could be detected. On the other hand, Goulart et al.^[29] found that Al_6Fe prevails for growth rates higher than 0.7 mm/s after performing experiments with hypoeutectic Al-Fe alloys under unsteady-state solidification conditions. Another investigation^[30] demonstrated that Al_3Fe is the predominant IMC phase in the Bridgman-grown samples over very low velocities of 50, 150, and 300 $\mu\text{m/s}$. Other studies^[4,31] reported that if cooling rates higher than 1.0 K/s are imposed, the metastable Al_6Fe IMC prevails in the eutectic mixture. The aforementioned studies suggest that mixed arrangements of such intermetallics is an ordinary occurrence in Al-Fe castings, and its microstructural transition is closely related to the thermal parameters imposed during solidification.

According to Allen et al.,^[25] a competitive nucleation may happen between one eutectic phase to another, i.e., Al- Al_3Fe to Al- Al_6Fe . Although such a transition may be considered still a matter of debate in the literature,^[25] experimental evidences show that in the absence of impurities, undercooling of $\sim 10 \pm 15$ K at cooling rates as low as 0.03 K/s are detected prior to the onset of Al- Al_3Fe eutectic solidification. This means that nucleation of this eutectic from the liquid by the surrounding solid Al matrix may not be considered facile. On the other hand, the Al- Al_6Fe eutectic needed no detectable undercooling to nucleate, indicating that Al is an efficient nucleant for this type of constituent.

Despite the importance of the solidification stage not only on the formation of Al-Fe intermetallics but also on the scale of cellular or dendritic arrays, few studies have been proposed with a view to correlating mechanical properties with microstructural features of Al-Fe alloys, such as the cellular/dendritic pattern or the distribution of the eutectic mixture and the IMC particles. Goulart et al.^[32] demonstrated that the tensile strength increases

with increasing Fe alloying and with a more homogeneous distribution of IMC Al_6Fe fibers. For coarser microstructural cellular arrangements, the Al_6Fe fibers remain more concentrated in the intercellular regions provoking a deleterious effect on the mechanical properties due to the brittle nature of these fibers. Both mechanical strength and corrosion resistance can be affected by the distribution of the eutectic constituent as well as the IMC type. Such features and their distributions are mainly associated with the scale of the microstructure. Cellular and dendritic growth may be affected by the alloy composition and cooling rate during solidification. Some recent studies have pointed out the effect of microstructure, and particularly of the scale of the dendritic array on the resulting mechanical properties.^[6–13]

The interdendritic/intercellular IMC phases are considered as control parameters for strength and elongation, as reported by Campbell.^[33] The size and distribution of these phases can affect the mechanical properties, especially considering systems containing hard, brittle, plate-like particles in a ductile matrix. The highly deleterious effect of iron impurities in Al alloys is attributed to the extensive platelike morphology of the iron-rich phases. Campbell^[33] also reported a close relation between secondary dendrite arm spacing (λ_2) and the iron-rich plate length, which means that as λ_2 is reduced, the plates become smaller. As a result, strength and toughness are correspondingly increased. In general, if the dendrite arm spacing is reduced, then the mechanical properties of the cast alloy are invariably improved.

Some recent studies in the literature reported that the macrostructural and microstructural morphologies have a strong influence on the corrosion resistance.^[14–19] According to Dorin and coauthors,^[26] aluminum and its alloys are prone to pitting corrosion due to the presence of secondary phases, such as Al_3Fe , AlFeMnSi , $\text{Al}_7\text{Cu}_2\text{Fe}$, and Al_2CuFeMn . These IMC particles are considered cathodic in nature and are well known to cause severe pitting.^[34–36]

Iron content in commercial Al alloys tends to increase during recycling. As a consequence, the recyclability of high-performance Al alloys, in which Fe is required to be lower than 0.1 wt%, becomes impractical. In this context, alternative processing technologies become necessary in order to decrease the detrimental effect of Fe in Al alloys, extending the limits of recycling. Dorin and coauthors^[26] affirmed that any casting technology enabling a more rapid cooling rate is known to result in refined microstructure, and therefore, a positive influence on the corrosion resistance is induced. These authors noted a remarkable improvement in the corrosion resistance of direct strip cast Al-Fe alloys, which was attributed to a decrease in size and volume fraction of Fe-intermetallics.

As observed by Verma et al.,^[37] the Fe intermetallics have a surprising and previously under-appreciated ability to adopt curved and convoluted morphologies around

dendrites, which can be expected to have a dramatic effect on mechanical properties, especially toughness. For instance, a decrease in cooling rate may provoke an increase in the relative fraction of $\beta\text{-AlFeSi}$ phase. The sizes identified for the $\alpha\text{-AlFeSi}$ particles were smaller at a high cooling rate (16.6 K/s), while large plates of $\beta\text{-AlFeSi}$ were found at slower cooling rates (about 1.1 K/s).

Griger et al.,^[31] studied the variation of iron in Al solid solution as a function of both the cooling rate and composition. It is well known that the solid solubility of iron in aluminum is very low under equilibrium conditions (0.04 wt%Fe). Griger and coauthors^[31] reported that the iron content increases from 0.041 wt% to 0.059 wt% when the cooling rate is increased from 1 to 500 K/s for Al–0.5 wt%Fe samples. Based on these results it can be inferred that supersaturation of iron in aluminum is very limited even for nonequilibrium solidification conditions. Gremaud et al.^[38] reported that under rapid solidification conditions (laser surface remelting—LSR process) of Al–Fe alloys cellular-dendritic structures, banded structures, and supersaturated solid solutions can be observed.

Laser surface treatments are efficient means of local transformation of mechanical and chemical properties.^[39–42] The laser surface remelting (LSR) process is accomplished by rapidly traversing a continuous, high-energy-density laser beam over the material to produce a thin molten layer at the material surface. The ability to maintain a cold substrate while melting a thin surface layer results in rapid quenching of the molten region once the energy source is removed, resulting in very high solidification cooling rates (up to about 10^8 K/s).^[41–46]

The interactions between a laser beam and an alloy surface is controlled by a number of variables. A particular combination of power density and interaction time defines a specific operational regime within the spectrum of operating conditions, which results in the occurrence of a unique materials processing effect. A number of studies existing in the literature examine the interaction between the laser energy and the substrate and the corresponding phase change in the irradiated region during surface treatments. Cheung et al.^[47] examined the LSR of an aluminum alloy by a mathematical heat transfer model based on the finite difference method. This model takes into account convection effects through the application of an effective thermal conductivity approach. Bertelli et al.^[48] applied a 3D numerical approach in the analysis of laser remelting of an Al–1.5 wt%Fe alloy permitting the analysis of temperature distribution and despite the typical high cooling rate process used, they reported the occurrence of a microstructure typified by a stable Al– Al_3Fe eutectic aligned with the growth direction.

In the present work, a careful technique of dissolution of the Al-rich phase is performed in hypoeutectic Al–Fe alloys samples, which were solidified under a wide range of cooling rates. The experiments were carried out with Al–0.5, –1.0, and –1.5 wt%Fe alloys, subjected to equilibrium

cooling from the melt; steady-state solidification (Bridgman growth); transient directional solidification in water-cooled and air-cooled molds; and rapid solidification (laser remelting). The distribution, shape, and chemical composition of the AlFe intermetallics are evaluated using characterization techniques such as optical microscopy, scanning electron microscopy, EDX microanalysis, and X-ray diffraction. The experimental results have permitted the analysis of different patterns of AlFe intermetallics and the correlation of type of intermetallics with the solidification cooling rate.

EXPERIMENTAL PROCEDURE

In order to examine the occurrence of different morphologies of Al-Fe intermetallics in as-cast Al-Fe alloys, different solidification experiments were performed encompassing an extensive range of solidification cooling rates. The main features of each experiment and its apparatus layouts are briefly described in the sections that follow. Details of the technique used to dissolve the Al-rich phase are also presented in the "Experimental Procedure/Classic Metallography and Dissolution Techniques" sections.

Equilibrium Solidification

Samples of Al-Fe alloys (1 and 3 wt%Fe) were solidified under a slow cooling rate (10^{-2} K/s), close to that of an equilibrium solidification condition, with the aim to produce equilibrium Al_3Fe intermetallics. The chemical compositions of metals used to prepare these alloys are presented in Table 1. The internal surface of a silicon carbide crucible was covered with an alumina layer in order to prevent iron attack. The Al-Fe alloy was contained in the crucible and melted in a muffle-type furnace (Fig. 1), which was switched off and left to naturally cool with its front door closed. The aforementioned cooling rate was obtained by collecting readings using a thermocouple placed inside the crucible.

Bridgman Growth

Al-0.5, -1.0, and -1.5 wt%Fe alloy samples were subjected to Bridgman steady-state directional solidification at growth velocities of 50, 150, and 300 $\mu\text{m/s}$ under an imposed thermal gradient of 1.5 K/mm. The Bridgman

furnace (Fig. 2) has three different heating zones of high thermal control accuracy. The highest temperature range is located at the bottom and the top of the furnace, which is insulated to prevent heat losses. As-cast alloy samples were machined to dimensions of 8 mm in diameter and 110 mm in length. The specimens were placed inside a boron nitride tube that moves across the three heating zones by an electronically controlled elevator. In order to achieve a thermal homogenization, the samples were initially held in the liquid state for 90 min and then were pulled down toward a cooler zone, where the solidification began. A provision for measurements of thermal profile during the growth process employed four type K thermocouples placed along the outside wall of the boron nitride tube, as indicated in Fig. 2.

Transient Directional Solidification

Hypoeutectic Al-Fe alloys (0.5, 1.0, and 1.5 wt%Fe) were directionally solidified (DS) under transient conditions through a device (Fig. 3) that promotes vertical upward directional solidification imposed by a water-cooled bottom made of low-carbon steel. This device consists of a furnace coated with a refractory material wall surrounded by a system of electrical resistances controlled by an electronic system. This system allows the temperature of the molten alloy to be adjusted in order to achieve a desired melt superheat. In the case of the present experiments, a superheat of 2°C above the *liquidus* temperature was reached before the onset of solidification. On the right side of Fig. 3, it can be seen a bank of type K thermocouples positioned with respect to the heat extracting surface. All thermocouples were connected by coaxial cables to a data logger interfaced with a computer, and the temperature data were automatically recorded. The inner surfaces of the cylindrical stainless steel mold were coated with aluminum oxide to prevent contamination of unwanted elements to the alloy by diffusion. The low-carbon steel mold at the bottom, from where the casting was cooled by blasting water, had a polished finish at the metal/mold surface contact. In order to permit the effect of a wider range of solidification cooling rates, thus permitting a wider spectrum of microstructures to be examined, air-cooled directional solidification experiments were also conducted.

Rapid Solidification

Al-1.5 wt%Fe alloy samples were subjected to a surface laser remelting process followed by rapid solidification when the laser beam moved away. As shown in Fig. 4, a sample, previously extracted from a DS casting obtained by upward directional solidification, was used for the laser treatment. The laser device employed was the Ytterbium Fiber Laser, model IPG YLR 2000S, which emits radiation at a wavelength of 1070 nm and has a maximum power of 2000 W. The diameter of the focused beam is

Table 1 Chemical composition of metals used to prepare the Al-Fe alloys

Metal	Chemical composition (wt%)					
	Fe	Si	Mn	Cu	Ni	Al
Al	0.09	0.06	—	0.06	0.03	99.8
Fe	99.9	0.01	0.05	0.01	0.01	—

Fig. 2 Schematic representation of the Bridgman furnace and of thermocouples locations along the crucible

about 100 μm . The laser head is fixed but a CNC driven XYZ table imposes movement to the sample, thus permitting to cover the whole area to be treated. The laser operation conditions during the surface remelting process were as follows: power of 600 W, laser beam speed of 40 mm/s, and laser beam defocused in 3 mm to enable a spot beam diameter of 300 μm . The sample surface was prepared by sandblasting in order to increase absorption of laser beam energy, since the reflectivity of aluminum alloys in polished condition is high.

Classic Metallography and Dissolution Techniques

The classic metallography procedures used in selected samples previously subjected to the aforementioned casting experiments, included grinding, electropolishing, and etching (with a solution of 0.5% HF in water). The examination of

the microstructures was performed using an optical Olympus Inverted Metallurgical Microscope (model 41GX). Microstructural characterization was complemented by the use of a ZEISS scanning electron microscope—SEM (ZEISS-EVO-MA15), equipped with an energy dispersive spectrometer—EDS (OXFORD-X-MAX).

The dissolution technique is based on the reaction of 1-butanol with aluminum forming a butoxide and producing hydrogen gas:

The dissolution of the Al-rich phase has been carried out at 117°C in distilled 1-butanol according to a quantitative analysis method proposed by Simensen et al.,^[49] which permits to separate the undissolved Al-Fe intermetallics from the aluminum-rich phase. A glassware apparatus was used to dissolve the Al-rich matrix and the Al-rich phase of the eutectic mixture, as shown in Fig. 5. The sample is placed in a beaker on a 0.45 μm porosity Teflon screen, allowing only Al-Fe IMC particles to remain. Sample dissolution occurs in distilled 1-butanol under an argon atmosphere (to prevent the entry of humid air). The presence of water in the reaction favors the formation of undesirable aluminum oxide on the sample surface blocking the Al dissolution process:

For this reason, butanol undergoes previous distillation in which it is dried once more by using an aluminum swarf. After dissolution, butanol and aluminum butoxides were conducted through a Teflon filter. The undissolved IMC particles on the Teflon filter were identified and analyzed using X-ray diffraction (Bragg-Brentano reflection geometry with $\text{CuK}\alpha$ radiation; $\lambda = 1.5418 \text{ \AA}$) by comparing the XRD patterns with crystallographic data from the

RESULTS AND DISCUSSION

Equilibrium Solidification

Figures 6–9 show different microstructural aspects of Al-Fe alloys solidified under equilibrium conditions. In Fig. 6, a slight partial dissolution of the Al-rich matrix permits to observe the initial stage of dissolution in which craters are formed from the cellular boundaries, whereas the IMC particles located in the intercellular regions are still hidden by the Al-rich phase.

Figure 7 shows an SEM image of a polished sample of an Al-3 wt%Fe alloy, where the Al-Fe IMC particles

are seen embedded in the Al-rich matrix. It is not possible to conclude whether the Al-Fe phase has either a platelike or a needlelike morphology. However, by analyzing the image of a deeper stage of dissolution of the Al-rich phase of an Al-1.0 wt%Fe alloy sample, shown in Fig. 8, the prevalence of the Al_3Fe intermetallics having a morphology of coarse plates can be clearly observed. It is worth noting that coarser plates can strongly contribute to the nucleation of microfissures in the material under loading conditions.

Some individual Al-Fe plates were extracted from an Al-1 wt%Fe alloy sample and subjected to measurements performed by an EDX microprobe and an atomic ratio of about 3:1 was found. This means that Al_3Fe has prevailed along the entire Al-1 wt%Fe alloy sample solidified under

equilibrium conditions. Figure 9 shows a particular case of an isolated Al_3Fe plate, having a ratio of about 2.7 to 1 between Al and Fe.

Bridgman Growth

The cooling rate ($\dot{T}$) of each Al-Fe alloy sample grown by the Bridgman technique was determined from the experimental values of pulling rate (v) adopted in each experiment and a parameterized temperature gradient (G): ($\dot{T} = G \cdot v$). While the experimental measurement of cooling rate during Bridgman growth provides critical thermal information, it is typically acquired at only a few key locations. Nonetheless, this is still one of the best experimental tools for probing actual steady-state solidification conditions.^[51]

Columnar macrostructures prevailed along the length of all the Bridgman grown samples (Al-0.5, 1.0, and 1.5 wt%Fe alloys). Figure 10 shows typical examples of optical microscopy images of Al-1.0 wt%Fe alloy samples associated with two different solidification cooling rates: 0.45 K/s (Fig. 10A) and 0.15 K/s (Fig. 10B). The α -Al matrix (bright areas) is shown to have a cellular morphology, whereas the eutectic mixture, located in the intercellular regions, is constituted by the α -Al phase and Al-Fe IMC particles (dark areas). However, the morphology of these IMCs is not clear. It can be seen, by comparing the microstructures of Fig. 10A,B, that the cooling rate has a significant effect on the scale of the α -Al matrix, represented by the spacing between the center of adjacent cells.

Figures 11–13 show results related to the IMC compounds forming the eutectic mixture of the Al-1.5 wt%Fe Bridgman samples. These results come from samples subjected either to dissolution procedures (Figs. 11 and 12) or to XRD analyses (Fig. 13). The samples of Fig. 13 were grown under solidification cooling rates of 0.075 K/s (bottom) and 0.45 K/s (top). The XRD patterns confirm the growth of the Al_3Fe intermetallics based on the characteristic X-ray peaks associated with this phase. However, despite the dominant IMC is shown to be Al_3Fe , for the sample related to the higher cooling rate, there are a few peaks associated with the Al_6Fe IMC. According to a previous study by Young and Clyne,^[24] the transition from the equilibrium eutectic Al/ Al_3Fe to the metastable Al/ Al_6Fe occurs also via an intermediate phase Al_5Fe , which has been mistaken in the literature for Al_6Fe . This intermediate IMC would precipitate under cooling rates in the range 0.5–6.0 K/s^[24]. One of the samples of the present study was grown under 0.45 K/s, which is quite close to this range, and this could explain the observed peaks that have been associated with the Al_6Fe IMC in Fig. 13.

Partial dissolution of the Al-rich matrix is shown to be sufficient to clearly characterize the morphology of the intermetallics of the eutectic mixture. Typical SEM images of a partially dissolved Al-1.5 wt%Fe alloy sample are shown in Fig. 11, emphasizing the prevalence of plate-like Al_3Fe IMC. In the case of complete dissolution of the Al-rich matrix, as shown in Fig. 12, the morphology and scale of the Al_3Fe particles can be clearly distinguished.

Transient Directional Solidification

The Al-0.5, -1.0, and -1.5 wt%Fe alloys were also subjected to transient directional solidification in the water-cooled apparatus, described in the “Experimental Procedure/Transient Directional Solidification” sections, and columnar macrostructures prevailed in all the DS castings. Some important microstructural features of the Al-Fe alloys experimentally examined, such as the arrangement and scale of the resulting cellular structure, can be observed by optical and electron microscopy of polished samples. Nevertheless, certain microstructural

Fig. 13 XRD patterns (Bragg–Brentano reflection geometry with $\text{CuK}\alpha$ radiation ($\lambda = 1.5418 \text{ \AA}$) of Al–1.5 wt%Fe alloy samples grown by the Bridgman technique under cooling rates of 0.45 K/s (top) and 0.075 K/s (bottom). The XRD patterns were compared with crystallographic data from the ICSD^[50]

remarks are only possible to be detected if the undissolved arrangement of intermetallics is preserved after the partial dissolution of the Al-rich phase. In this sense, typical SEM transverse microstructures of the DS Al–Fe alloy castings associated with both position in casting and local solidification cooling rate, highlighting the intermetallics along the cellular boundaries, are exemplified in Fig. 14. The intercellular areas contain the eutectic mixture characterized by aligned Al_6Fe fibers, which appear to be anchored in the Al-rich matrix. The higher magnification image shows a detail of a quasi-hexagonal arrangement, typical of cellular structures. These microstructures prevailed along all the length of the Al–Fe alloy DS castings, with the IMC particles having a rodlike configuration.

Although the interphase spacing could be measured using SEM images on polished samples, as shown in Fig. 14, such measurements can be more accurate if samples with the Al-rich phase completely dissolved are used, as shown in Fig. 15. Furthermore, deeper investigations on the skeletal arrangement of Al_6Fe IMC fibers can be conducted, permitting the presence of faults, branching, ending, and change in fiber diameter to be characterized in detail.

As shown in Fig. 15, the Al_6Fe eutectic fibers are interconnected and better mechanical properties can be expected as compared with microstructures having platelike Al–Fe IMC fibers, which are not connected. This Al_6Fe skeleton seems to have a reinforcing role with respect to the ductile Al-rich matrix, which is even better for decreasing cell

Fig. 14 Typical SEM images of Al-Fe hypoeutectic alloys along the length of the DS castings. Example of the Al-1 wt%Fe alloy casting with images being correlated with both position and cooling rate: bright areas represent the Al-Fe IMCs of the eutectic mixture along the boundaries of the Al-rich cells (dark areas). SE: partially dissolved sample and BSE: not-dissolved sample

Fig. 15 Typical SEM images of hypoeutectic Al-Fe alloy samples with the Al-rich phase completely dissolved, characterized by interconnected Al₃Fe fibers (bright areas). SE: secondary electron mode

Fig. 16 A typical SEM image of hypoeutectic Al-Fe alloys at positions closer to the top of the DS castings (Al-1.0 wt%Fe alloy casting at 95 mm from the cooled bottom): coarser Al_3Fe particles can be seen mixed with the Al_6Fe rodlike fibers along the cells boundaries. SE: secondary electron mode

size, since a more homogeneous distribution of the IMC particles occurs.^[52–53] In spite of that, Al_6Fe fibers have shown a tendency to cross link with decreasing cooling rates. A similar behavior has been reported by Hughes and Jones,^[54] who studied a range of compositions of Al-Fe alloys from 2.2 to 6.1 wt%Fe and found increase in linking of rods with decreasing growth rates and increasing Fe concentration.

The entire set of optical microstructures characterized along the length of the DS castings, gives indications that regions of coexistence of Al_3Fe and Al_6Fe IMCs in the eutectic mixture exist for cooling rates <1.5 K/s (corresponding to positions in the DS castings >75 mm from the cooled bottom). In Fig. 16, the coarser Al_3Fe particles can be seen mixed with the Al_6Fe rodlike fibers along the cells boundaries.

With a view to confirming the composition of the Al-Fe IMC particles prevailing in the eutectic mixture along the DS castings, samples were subjected to both EDX and X-ray diffraction analyses. Figure 17 shows results of EDX microprobe analyses along the microstructure of an Al-1.0 wt%Fe alloy, after partial dissolution of the Al-rich phase, i.e., point 2: the primary Al-rich phase, and points 1 and 3:

Fig. 17 SEM micrograph of an Al-1.0 wt%Fe alloy after partial dissolution of the Al-rich phase. Points 1, 2, and 3 indicate local atom concentration of Al/Fe obtained by EDX microprobe analyses: point 2: the primary Al-rich phase and points 1 and 3: Al-Fe fibers. BSE: backscattered electron mode

Al-Fe fibers with the atom concentration indicating a ratio of 6.8 to 1 between Al and Fe. This ratio is very close to that expected to be found in Al_6Fe IMCs.

Typical examples of XRD patterns of Al-Fe samples for positions close to the cooled bottom (P1) and closer to the top of the DS casting (P7) are shown in Fig. 18. Many peaks characterizing the Al_6Fe phase have been found for any hypoeutectic Al-Fe alloy examined. The X-ray powder diffraction technique usually requires some sample preparation, i.e., crushing the sample, or rolling it into a very thin rod, or spreading it as a thin layer on a sample holder. This could not be done with the undissolved particles due to their reduced amount. These particles were then packed into a sample holder by using a membrane filter as a support. The observed differences among the number of peaks shown in Fig. 18 can be attributed to the size and packing density of the undissolved particles.

Figure 19 shows the evolution of the cellular spacing (λ_1) with the cooling rate ($\dot{T}$) for the DS samples for all hypoeutectic Al-Fe alloys experimentally evaluated in both steady-state (Bridgman) and transient solidification.^[30] The unsteady-state solidification apparatus was also adapted with an air-cooled mold, with a view to permit an additional experiment with the Al-1.5 wt%Fe alloy to be carried out. As indicated in Fig. 19, the prevalence of Al_6Fe intermetallics embedded into the aluminum matrix occurred for cooling rates higher than 1.5 K/s. Young and Clyne^[27] carried out unidirectional solidification experiments with hypoeutectic Al-Fe alloys under steady-state heat flow conditions, and reported that Al_6Fe prevailed for cooling rates >3.0 K/s.

Miki et al.^[55] carried out transient solidification experiments of Al-0.25 wt%Fe and Al-0.55 wt%Fe alloys over a wide range of cooling rates. These alloys were cast into wedge-shaped molds made of aluminum and cast iron. They found the prevalence of Al_6Fe particles for a cooling rate range between 1.0 and 10 K/s, which is fairly close to the results found in the present study.

Fig. 18 Typical examples of XRD patterns (Bragg–Brentano reflection geometry) with CuK α radiation ($\lambda = 1.5418 \text{ \AA}$) of hypoeutectic Al–Fe alloys samples: (A) bottom and (B) top of the DS castings. The XRD patterns were compared with crystallographic data from the ICSD^[50]

Fig. 19 Correlation between cellular spacing and cooling rate during directional solidification of hypoeutectic Al–Fe alloys (steady-state and transient solidification). The prevalence of either Al_3Fe or Al_6Fe particles is delimited as a function of the solidification cooling rate

Rapid Solidification

In order to investigate the microstructural evolution of a hypoeutectic Al–Fe alloy under conditions of rapid solidification, samples extracted from a DS Al–1.5 wt%Fe alloy casting, similar to those obtained in the “Results and Discussion/Transient Directional Solidification” sections, have been subjected to a laser remelting process, as described in the “Experimental Procedure/Rapid Solidification” sections. The substrate is then characterized by a cellular microstructure with the eutectic mixture located along the cells boundaries and a eutectic mixture formed by the Al-rich phase and Al–Fe IMC particles characterized the resolidified pool, as shown by the SEM image in Fig. 20. The remarkable change in the scale of the microstructures on both sides of the interface-treated sample/substrate can be observed in the higher magnification image on the right side of Fig. 20. The characteristic microstructural spacing varied from about 13 μm in the substrate (non-treated zone) to spacings lower than 1.0 μm in the resolidified zone. Considering the experimental growth law of Fig. 19 ($\lambda = 31 \dot{T}^{-0.55}$), the solidification cooling rates associated with these microstructural spacings would be about 5 K/s and 3×10^3 K/s, for substrate and treated zones, respectively.

Figure 21B shows a typical microstructure of the laser-treated region, in which the Al-rich matrix was partially dissolved with a view to highlighting the Al–Fe IMC. These particles seem to have a platelike character instead of rodlike fiber morphology, typical of the Al_6Fe fibers shown in the “Results and Discussion/Transient Directional Solidification” sections. It has been reported that with the increase in the solidification velocity, the Al_3Fe equilibrium phase is first replaced with the metastable Al_6Fe and at a high velocity regime with Al_mFe ($m \sim 3.96$).^[31,48] Griger et al.^[31] obtained Al–Fe samples by

a few experimental procedures so that samples solidified under a wide spectrum of cooling rates could be examined. These samples were subjected to X-ray powder diffraction measurements with a Guinier-Hagg camera and a goniometer equipped with a graphite monochromator, using chromium and copper radiation, permitting the IMC compounds to be identified. For cooling rates around 10^3 K/s and considering the Al–1.5 wt%Fe alloy, the Al_mFe intermetallics ($m \sim 3.96$) was shown to prevail. Gilgien et al.^[56] carried out laser remelting experiments with an Al–Fe alloy at a laser beam speed of 10 mm/s and reported that, except for a dendritic Al-rich matrix at the top of the laser trace, the resolidified layer was formed by an Al– Al_6Fe eutectic which followed the growth direction. As shown in Fig. 21A, no evidence of dendritic microstructure has been found in the laser-treated region, whereas the eutectic structure is also aligned with the growth direction. The platelike IMC (light areas) was shown to be Al_3Fe according to the X-ray diffractogram of Fig. 22. It is often considered that at high cooling rates, kinetic restrictions avoid the atoms to arrange themselves in a stable structure.^[55] Furthermore, the evolution of solidification microstructures along the laser remelting process has some particular aspects. The laser melted pool is contained by its own solid and during cooling no nucleation is involved and an epitaxial solidification occurs. It is worth noting that the onset of solidification at the interface between molten pool and substrate is characterized by very low solidification velocities and cooling rates,^[56] thus contributing to the initial formation of the stable Al– Al_3Fe eutectic. It is quite possible that such eutectic continues to grow despite the sudden increase in the solidification velocity from the bottom to the surface of the pool, i.e., the equilibrium Al_3Fe is not replaced with increasing solidification velocity with a metastable aluminide. This could explain the presence of the Al– Al_3Fe eutectic.

CONCLUSIONS

Although the microstructural interphase spacing of hypoeutectic Al-Fe alloys could be measured using SEM images on polished samples, such measurements can be more accurate if samples with the Al-rich phase completely dissolved are used. Furthermore, deeper investigations on the skeletal arrangement of either Al_6Fe IMC fibers or Al_3Fe plates can be conducted, permitting the presence of faults, branching, ending, and changes in size, as a function of solidification cooling rate, to be characterized in detail. If a refined observation of the cross-linked arrangement of Al_6Fe particles is desired, SEM images of

the extracted intermetallics obtained by the dissolution method were shown to be more appropriate.

In the present investigation, for experiments with hypoeutectic Al-Fe alloys under equilibrium, steady-state, and transient solidification conditions, it was shown that the solidification cooling rate is the main feature determining the type of Al-Fe intermetallics in the eutectic mixture. It was shown that Al_6Fe prevails for cooling rates >1.5 K/s, and that a short zone of coexistence of Al_3Fe and Al_6Fe phases exists for cooling rates <1.5 K/s, which is rapidly replaced with the prevalence of the Al_3Fe intermetallics with further decrease in cooling rate. In contrast, even with the high values of cooling rates of a laser remelting process, the microstructure of

Fig. 22 XRD patterns (Bragg–Brentano reflection geometry with CuK α radiation ($\lambda = 1.5418 \text{ \AA}$) of laser treated Al–1.5 wt%Fe alloy samples. The XRD patterns were compared with crystallographic data from the ICSD^[50]

a laser-treated Al–Fe sample was shown to be formed by the Al–Al₃Fe eutectic, which followed the direction of the growth rate. This has been attributed to specific aspects of this process, epitaxial solidification and kinetic restrictions.

Image Processing for Fault Detection in Aluminum Castings

Domingo Mery, Dieter Filbert, and Thomas Jaeger

Abstract

In this article, a review of the use of image processing as a tool in the automated visual inspection of aluminum castings is provided. Methodologies and principles are outlined. This discussion includes detained overviews of: digital image processing in x-ray testing and defect detection in castings.

Keywords: Castings; Defect detection; Image analysis; X-ray testing.

INTRODUCTION

Shrinkage occurs as molten metal cools during the manufacture of die-castings, which can cause nonhomogeneous regions within the work piece. These are manifested, for example, by bubble-shaped voids or fractures. Voids occur when the liquid metal fails to flow into the die or flows in too slowly, whereas fractures are caused by mechanical stresses when neighboring regions develop different temperature gradients on cooling. Other possible casting defects include inclusions or slag formation.

Light-alloy castings produced for the automotive industry, such as wheel rims, steering knuckles, and steering gear boxes, are considered important components for overall roadworthiness. To ensure the safety of construction, it is necessary to check every part thoroughly.^[1–3]

Radioscopy rapidly became the accepted way for controlling the quality of die cast pieces through visual or computer-aided analysis of x-ray images. The purpose of this nondestructive testing (NDT) method is to identify casting defects, which may be located within the piece and thus are undetectable to the naked eye. An example of such defects in a light-alloy wheel is shown in the x-ray image in Fig. 1. The automated visual inspection of castings is a quality control task to determine automatically whether a casting complies with a given set of product and product safety specifications.

Over the past decades radioscopic systems have been introduced in the automotive industry that detect flaws without human interaction, i.e., automatically.^[4–6] Compared to a manual evaluation of x-ray images, automated detection of casting defects offers the advantages of objectivity and reproducibility for every test. Fundamental disadvantages of the methods proposed to date are the complexity of their configuration and inflexibility to any changes in the design of the work piece, which is something that people can accommodate easily. Research and development is, however, ongoing into automated adaptive processes to accommodate design modifications.

In recent years, automated radioscopic systems have not only raised quality, through repeated objective inspections and improved processes, but have also increased productivity and profitability by reducing labor costs.^[7]

The principal aspects of an automated x-ray inspection unit are shown in Fig. 2. Typically, it comprises the following five steps:^[8]

1. A *manipulator* for handling the test piece.
2. An *x-ray source*, which irradiates the test piece with a conical beam to generate an x-ray image of the test piece.
3. An image intensifier which transforms the invisible x-ray image into a visible one.
4. A CCD camera which records the visible x-ray image.
5. A computer to process the digital image processing of the x-ray image and then classifies the test piece accepting or rejecting it. The computer may also control the manipulator for positioning the test piece in the desired inspection position, although this task is normally performed by a programmable logic controller (PLC).

Nowadays, flat amorphous silicon detectors are used as image sensors in some industrial inspection systems.^[9,10] In such detectors, using a semi-conductor, energy from the x-ray is converted directly into an electrical signal (without image intensifier). However, NDT using flat detectors is less feasible due to their higher cost in comparison to image intensifiers.

In this chapter, we will discuss the use of image processing as a tool in the automated visual inspection of aluminum castings. Our chapter is organized as follows. Section 2 introduces the reader to the image processing theory employed when inspecting aluminum castings. Methodologies and principles will be outlined. Some application examples are given followed by the limitations of the applicability of the methodologies used. Section 3 presents a survey of many of the automated visual inspection approaches adopted for aluminum castings that have

Fig. 1 Voids in radioscopic images of aluminum wheels

Fig. 2 Schematic diagram of an automated x-ray testing stand

been reported since 1985. Section 4 concludes and offers suggestions for future research. Finally, a bibliography provides references for further reading.

DIGITAL IMAGE PROCESSING IN X-RAY TESTING

Two classes of regions are possible in a digital x-ray image of an aluminum casting: regions belonging to regular

structures of the specimen, and those relating to defects. In the computer-aided inspection of castings, our aim is to identify these two classes automatically using pattern recognition techniques.

The automatic pattern recognition process used in fault detection in aluminum castings, as shown in Fig. 3, consists of five steps. The first is image formation, in which an x-ray image of the casting under test is taken and stored in the computer. In the second step, *image preprocessing*, the quality of the x-ray image is improved in order to enhance

Fig. 3 Phases of pattern recognition in automated flaw detection

the details of the x-ray image. The third one is called image segmentation, in which each region of the x-ray image is found and isolated from the rest of the scene. The fourth step is the feature extraction. This is where the regions are measured and some significant characteristics are quantified. The fifth step of the fault detection is classification. The extracted features of each region are analyzed and assigned to one of the classes (regular structure or defect).

In this section we provide an overview of these five steps. Methodologies and principles will be outlined. Some application examples followed by limitations to the applicability of the used methodologies will be presented. Finally, we give an introduction to simulation of defects in x-ray images, that is normally used in order to evaluate the performance of a method that inspects castings.

Image Formation

In x-ray examination, x-ray radiation is passed through the material under test, and a detector senses the radiation intensity attenuated by the material. A defect in the material modifies the expected radiation received by the sensor.^[11] This phenomenon, called *differential absorption*, is illustrated in Fig. 4.

Fig. 4 Differential absorption in a specimen

Fig. 5 Image formation process: (a) x-ray image of a wheel with two defects, (b) 3D plot of the gray values of the image

The contrast in the x-ray image between a flaw and a defect-free area of the specimen is distinctive. In an x-ray image we can see that the defects, such as voids, cracks, or bubbles, show up as bright features. The reason is that the attenuation in these areas is shorter. Hence, according to the principle of differential absorption, the detection of flaws can be achieved automatically using image processing techniques that are able to identify unexpected regions in a digital x-ray image. A real example is shown in Fig. 5 which depicts two defects clearly.

The x-ray image is usually captured with a frame-grabber and stored in a matrix. An example of a digitized x-ray image is illustrated in Fig. 6. The size of the image matrix corresponds to the resolution of the image. In this example the size is 286×384 picture elements, or *pixels*. Each pixel has associated a *gray value*. This value is between 0 and 255 for a scale of $2^8 = 256$ gray levels. Here, '0' means 100% black and a value of '255' corresponds to 100% white, as illustrated in Fig. 7. Let matrix x be the digitized x-ray image, then the element $x(i, j)$ denotes the gray value of the i th row of the j th column, as shown in the matrix of Fig. 6. The eye is only capable of resolving around 40 gray levels;^[12] however, for the detection of defects in aluminum castings, gray level resolution must be a minimum of 256 levels.

Fig. 6 Digital x-ray image

Fig. 7 256 gray level scale

In some applications, $2^{16} = 65,536$ gray levels are used,^[9] which allows one to evaluate both very dark and very bright regions in the same image.

Preprocessing

The x-ray image taken must be preprocessed to improve the quality of the image before it is analyzed. In this section, we will discuss preprocessing techniques that can remove noise, enhance contrast, correct the shading effect, and restore blur deformation in x-ray images.

Noise Removal

Noise in an x-ray image can prove a significant source of image degradation and must be taken into account during image processing and analysis. In an x-ray imaging system, *photon noise* occurs given the quantum nature of x-rays. If we have a system that receives μ photons per pixel in a time ΔT on average, the number of photons striking any particular pixel in any time ΔT will be random. At low levels, however, the noise follows a Poisson law, characterized by the probability

$$p(x|\mu) = \frac{e^{-\mu} \mu^x}{x!} \quad (1)$$

to obtain a value x of photons given its average μ photons in a time ΔT . The standard deviation of this distribution is equal to the square root of the mean.* This means that the photon noise amplitude is signal-dependent.

*At high levels, the Poisson distribution approaches the Gaussian with a standard deviation equal to the square root of the mean: $\sigma = \sqrt{\mu}$.

Integration (or averaging) is used to remove x-ray image noise. This technique requires n stationary x-ray images. In this technique, the x-ray image noise is modeled using two components: the stationary component (that is constant throughout the n images) and the noise component (that varies from one image to the next). If the noise component has zero mean, by averaging the n images the stationary component is unchanged, while the noise pattern decreases by increasing n . Integrating n stationary x-ray images improves the signal-to-noise ratio by a factor of $\sqrt{n}$.^[4,12]

The effect of image integration is illustrated in Fig. 8 that uses n stationary images of an aluminum casting and shows the improvement in the quality of the x-ray image.

The larger the number of stationary images n , the better the improvement. Normally, between 10 and 16 stationary images are taken ($10 \leq n \leq 16$).

Contrast Enhancement

The gray values in some x-ray images lie in a relatively narrow range of the gray scale. In this case, enhancing the contrast will amplify the differences in the gray levels of the image.

We use a gray level histogram to investigate an x-ray image's gray scale. The function summarizes the gray level information of an x-ray image. The histogram is a function $h(x)$ where x is a gray level and $h(x)$ denotes the number of pixels in the x-ray image that have a gray level equal to x . Figure 9 shows how each histogram represents the distribution of gray levels in the x-ray images.

A transformation can be applied to modify the distribution of gray level in an x-ray image. Simple contrast enhancement can be achieved if we use a linear transformation which sets the minimal and maximal gray values

Fig. 8 Noise removal after an averaging of n frames. The noise is reduced by factor $\sqrt{n}$

of the x-ray image to the minimal and maximal gray value of the gray level scale respectively. Thus, the histogram is expanded to occupy the full range of the gray level scale. Mathematically, for a scale between 0 and 255, this transformation is expressed as:

$$y(i, j) = 255 \frac{x(i, j) - x_{\min}}{x_{\max} - x_{\min}} \quad (2)$$

where $x_{\min}$ and $x_{\max}$ denote the minimal and maximal gray value of the input x-ray image. The output image is stored in matrix y . Figure 9b shows the result of the transformation applied to the x-ray image in Fig. 9a. We observe in the histogram of the enhanced x-ray image how the gray levels expand from '0' to '255'. The mapping is linear, and means that a gray value equal to $(x_{\max} - x_{\min})/2$ will be mapped to

255/2. This linear transformation is illustrated in Fig. 10a, where the abscissa is the input gray value and the ordinate is the output gray value.

In a similar fashion, gray input image values can be mapped using a nonlinear transformation $y = f(x)$, as illustrated in Fig. 10b and Fig. 10c, whose results are shown in Fig. 9c and 9d, respectively. The nonlinear transformation is usually performed with a γ correction.^[13] In these examples, if $\gamma > 1$ the mapping is weighted toward darker output values, and if $\gamma < 1$ the mapping is weighted toward brighter output values.

Finally, we present a contrast enhancement equalizing the histogram. Here, we can alter the gray level distribution in order to obtain a desired histogram. A typical equalization corresponds to the uniform histogram as shown in Fig. 9d. We see that the number of pixels in the x-ray image for each gray level is constant.

Fig. 11 Shading correction: (a) original image, (b) image after shading correction. The corresponding gray value profiles of row number 130 are shown above the images

Fig. 12 Shading correction: (a) x-ray image for a thin plate, (b) x-ray image for a thick plate

Shading Correction

A decrease in the angular intensity in the projection of the x-rays causes low spatial frequency variations in x-ray images.^[4,6] An example is illustrated in Fig. 11a, which shows an x-ray image of an aluminum plate with holes in it. Since the plate is of a constant thickness, we would

expect to see a constant gray value for the aluminum part and another constant gray value for the holes. In fact, the x-ray image is darker at the corners. This deficiency can be overcome by using linear shading correction.

In this technique, we take two images as shown in Fig. 12. The first one, r_1 , of a thin plate, and the second one, r_2 , of a thick plate. We define i_1 and i_2 as the ideal gray

values for the first and second image, respectively. From r_1 , r_2 , i_1 , and i_2 , offset and gain correction matrices a and b are calculated assuming a linear transformation between the original x-ray image x and corrected x-ray image y :

$$y(i, j) = a(i, j)x(i, j) + b(i, j) \quad (3)$$

where the offset and gain matrices are computed as follows:

$$a(i, j) = \frac{i_2 - i_1}{r_2(i, j) - r_1(i, j)} \quad b(i, j) = i_1 - r_1(i, j)a(i, j) \quad (4)$$

An example of this technique is illustrated in Fig. 11b. In this case we obtain only two gray values (with noise), one for the aluminum part and another for the holes of the plate.

Restoration of Blur Caused by Motion

Image reconstruction involves recovering detail in severely blurred images, which is possible when the causes of the imperfections are known a priori.^[14] This knowledge may exist as an analytical model, or as a priori information in conjunction with knowledge (or assumptions) of the physical system that provided the imaging process in the first place.^[15] The purpose of restoration then is to estimate the best source image, given the blurred example and some a priori knowledge.

This section deals with blur caused by uniform linear motion, resulting from motion of the detector and/or the object.* The method we examine here is a new technique for the correction of blur.^[18] It assumes that the linear motion corresponds to an integer number of pixels and is horizontally (or vertically) aligned with sampling raster.

The proposed approach can be summarized as follows: given a gray value vector g , the row of the digitized degraded x-ray image; the unknown to be recovered is f , the corresponding restored row of the image. The relationship between these two components is $Hf = g$, which will be used as the constraint. The matrix H is known or it can be estimated from the degraded image using its Fourier spectrum.^[19,20]

Vector g is of N entries, while vector f is of $M = N + n - 1$ entries ($M > N$), where n is the length of the blurring process in pixels. The problem consists of solving the underdetermined system $Hf = g$. However, as an infinite number of exact solutions exist for f that satisfy $Hf = g$, an additional criterion is needed to find a sharp restored image: the proposed solution is defined as the vector, in the solution space of the underdetermined system, whose first N components has the minimum distance to the measured data, i.e., $\|f - g\| \rightarrow \min$, where f corresponds to the first N elements of f . A fast non-iterative algorithm for

Fig. 13 Restoration in simulated degraded x-ray images for different lengths of the blurring process in pixels

solving the underdetermined linear system under the mentioned constraint is developed in Ref. [18] using Lagrange multipliers.^[14] Here, f is estimated with:

$$\hat{f} = [\lambda H^T \cdot H + P^T \cdot P]^{-1} [\lambda H + P]^T g \quad (5)$$

with P a $N \times M$ matrix that is defined as $P = [I \mid 0]$, where I is a $M \times N$ identity matrix and 0 is a $N \times (n - 1)$ matrix whose elements are equal to zero. On using Lagrange multipliers, λ is assumed to be a very large number.

The procedure is repeated for each row of the degraded image. The restoration quality is equally as good as classical methods (see, e.g., Refs. [19,20]), while the computation load is decreased considerably. An example is shown in Fig. 13. Details of the aluminum castings are not discernible in the degraded images, but are recovered in the restored image.

Segmentation

Image segmentation is defined as the process of subdividing an image into disjointed regions.^[12] In image processing for detecting faults in castings, such regions correspond to potential defects and the background (or regular structures). While there are many methods for segmenting images, two approaches for segmenting potential defects in x-ray images are used widely within the nondestructive testing community. The first technique is based on median filtering while the second is a region-oriented method.

*Other algorithms for restoration of x-ray images are given in Refs. [16,17].

Fig. 14 Digital image filtering

Median Filtering

2D filtering is performed in digital image processing using a small neighborhood of a pixel $x(i, j)$ in an input image to produce a new gray value $y(i, j)$ in the output image, as shown in Fig. 14. A *filter mask* defines the input pixels to be processed by an *operator* f . The resulting value is the output pixel. The output for the entire image is obtained by shifting the mask over the input image. Mathematically, the image filtering is expressed as:

$$y(i, j) = f(x(i-p, j-p), \dots, x(i, j), \dots, x(i+p, j+p)) \quad (6)$$

for $i = 1, \dots, N$ and $j = 1, \dots, M$ where N and M are the number of rows and columns of the input and output images. The size of the filter mask is, in this case, $(2p+1) \times (2p+1)$. The operator f is linear, if the resulting value $y(i, j)$ is calculated as a linear combination of the input pixels:

$$y(i, j) = \sum_m \sum_n h(i-m, j-n) x(i, j) \quad (7)$$

where h is called the *convolution mask*. The elements of h weight the input pixels. Averaging is a simple example of linear filtering. For a 3×3 neighborhood, the convolution mask is

$$h = \frac{1}{9} \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}$$

Filtering out defects detected in an x-ray image of aluminum castings will provide a reference *defect-free* image. The defects are detected by finding deviations in the original image from the reference image. The problem is how one can generate a defect-free image from the original x-ray image. Assuming that the defects will be smaller than the regular structure of the test piece, one can use a low pass filter that does not consider the high frequency components of the image. However, if a linear filter is used for this task, the edges of the regular structure of the specimen are not necessarily preserved and many false alarms are raised at the edges of regular structures.

Consequently, a nonlinear filter is used. Defect discrimination is normally performed with a *median filter*. The median filter is a ranking operator (and thus nonlinear) where the output value is the middle value of the input values ordered in a rising sequence.^[12] For an even number of input numbers the median value is the arithmetic mean of the two middle values.

Fig. 15 Median filter application on a 1D signal. The size of the median mask is nine

Fig. 16 Median filter application on an $n \times n$ structure using an $m \times m$ quadratic mask compared to average and Gauss low pass filter application

Fig. 17 Defect detection using median filtering: (a) original x-ray image, (b) filtered x-ray image, (c) difference image, (d) binary image using a threshold, (e) eroded image, (f) dilated image superimposed onto original image

The application of a median filter is useful for generating the reference image because it smoothes noise yet preserves sharp edges, whereas other linear low pass filters blur such edges. Hence, it follows that small defects can be suppressed while the regular structures are preserved. Figure 15 shows this phenomenon for a 1D example. The input signal x is filtered using a median filter with nine input elements, and the resulting signal is y . We can see that structures of length n greater than four cannot be eliminated. The third column shows the detection $x - y$. Large structures of $n \geq 5$ not detected, as presented in the last two cases.

If the background captured by the median filter is constant, foreground structures could be suppressed if the number of values belonging to the structure is less than one half of the input value to the filter. This characteristic is utilized to suppress the defect structures and to preserve the design features of the test piece in the image.

An example for the application of a median filter on 2D signals (images) is shown in Fig. 16 and includes different structures and mask sizes compared to the effects of two linear low pass filters. One can appreciate that only the median filter manages to suppress the relatively small structures completely, whereas the large patterns retain their gray values and sharp edges.

The goal of the background image function, therefore, is to create a defect-free image from the test image.

A real example is shown in Fig. 17. In this example, from an original x-ray image x we generate a filtered image y and a difference image $|x - y|$. By setting a threshold, we obtain a binary image whose pixels are “1” (or white), where the gray values in the difference image are greater than the selected threshold. After an erosion and dilation technique we discard isolated pixels that do not conform a large enough region.^[12,13] The remaining pixels correspond to the detected flaws. Modifications of the median filter will be explained later in Section 3.1.1.

Edge Detection and Region Finding

This approach attempts to detect the potential defects in an x-ray image in two steps: *edge detection* and *region finding*.^[21,22] In the first step, the *edges* of the x-ray image are detected. The edges correspond to pixels of the image in which the gray level changes significantly over a short distance.^[12] The edges are normally detected using gradient operators. In the second step, the regions demarcated by the edges are extracted. The key idea of this two step based approach is that the existing defects present significant gray level changes compared to their surroundings. A Laplacian of Gaussian (LoG) kernel and a zero crossing algorithm^[12,23,24] can be used to detect the edges of the x-ray images. The LoG-operator involves a Gaussian low

Fig. 18 LoG-operator: (a) original x-ray image; edge detection with (b) $\sigma = 0.8$, (c) $\sigma = 13$, and (d) $\sigma = 2.5$

Fig. 19 Segmentation by edge detection and region finding: (a) original x-ray image, (b) second derivate using LoG-operator, (c) zero-crossing image, (d) and (e) detected regions

pass filter, which is good for the pre-smoothing of the noisy x-ray images. The LoG-kernel is defined as the Laplacian of a 2D-Gaussian function:

$$h_{\text{LoG}}(m,n) = \frac{1}{2\pi\sigma^4} \left(2 - \frac{m^2 + n^2}{\sigma^2} \right) \exp\left(-\frac{m^2 + n^2}{2\sigma^2}\right) \quad (8)$$

The parameter σ defines the width of the Gaussian function and, thus, the amount of smoothing and the edges detected (see Fig. 18). Using Eq. 7 we calculate an image in which the edges of the original image are located by their zero crossing. The detected edges correspond to the maximal (or minimal) values of the gradient image. The binary edge image obtained should reproduce real flaws' closed and connected contours that demarcate *regions*. Figure 19 illustrates the results obtained on an x-ray image by applying this method.

Feature Extraction and Selection

Segmented potential defects frequently set off false alarms. An analysis of the segmented regions, however, can improve the effectiveness of fault detection significantly. Measuring certain characteristics of the segmented regions (*feature extraction*) can help us to distinguish the false alarms, although some of the features extracted are either irrelevant or are not correlated. Therefore, a *feature selection* must be performed. Depending on the values returned for the selected features, we can try to classify each segmented region in one of the following two classes: *regular structure* or *defect*. In this section we concentrate on the extraction and selection of features, whereas in the next section we will discuss the classification problem.

Feature Extraction

In this section, we will explain the features that are normally used in the classification of potential defects. In our

description, features will be divided into two groups: *geometric* and *gray value* features.* We will use Fig. 20 as our example in the description of the features.

Geometric Features: Provide information on the size and shape of the region. Size features, such as area, perimeter, height, and width, are given in pixels. For example, in the region of Fig. 20, the area and the perimeter are $A = 45$ and $L = 24$ pixels, respectively. Shape features are usually attributed coefficients without units. An example is roundness that is defined as:

$$R = \frac{4A\pi}{L^2} \quad (9)$$

The roundness R is a value between 1 and 0. $R = 1$ means a circle, and $R = 0$ corresponds to a region without area. In our example $R = 0.98$.

Other shape features are obtained by calculating the central moments of the regions, and the *Hu moments*.^[26,27] These normalized moments are invariant under magnification, translation, and rotation of the region.

Fourier descriptors may also be a good choice for establishing the shape of a region.^[28] They are computed as the discrete Fourier transformation of the boundary's coordinates.

Gray Value Features: Gray value features provide information on the brightness of the region. The mean gray value is defined by

$$G = \frac{1}{A} \sum_{i,j \in \mathfrak{R}} x[i,j] \quad (10)$$

where $\mathfrak{R}$ is the set of pixels of the region, A the area, and $x(i,j)$ the gray level of pixel (i,j) . A 3D representation of the gray values of the region and its neighborhood of our

*A detailed description of these features can be found in Ref. [25].

Fig. 20 Example of a region: (a) x-ray image, (b) segmented region, (c) 3D representation of the gray values

example is shown in Fig. 20c. In this example, “0” means 100% black and “255” corresponds to 100% white. Similarly, one can compute the mean gradient in the boundary and the mean second derivate in the region. The first feature provides information about the changes in the gray values at the boundary of the region, whereas the second indicates whether the region is brighter or darker than its surroundings.^[25]

Contrast is a very important feature in fault detection, as the differences in the gray values are good for distinguishing a region from its neighborhood. The smaller the gray value difference, the smaller the contrast. There are, however, many definitions of contrast. Some are given in Ref. [29]:

$$C_1 = \frac{G - G_N}{G_N}, \quad C_2 = \frac{G - G_N}{G + G_N}, \quad \text{and} \quad C_3 = \ln(G / G_N) \quad (11)$$

where G and G_N denote the mean gray value in the region and in the neighborhood respectively. Figure 20 is an example of a high contrast region. Additional characteristics are *texture features* that take into account the distribution of the gray values in the region.^[12,30] Texture features can characterize defects very well, but are heavy on computing time.

Feature Selection

In feature selection we have to decide just which features of the regions are relevant to the classification. The n extracted features are arranged in an n -vector: $\mathbf{w} = [w_1 \dots w_n]^T$ that can be viewed as a point in a n -dimensional space. The features are normalized as:

$$\tilde{w}_{ij} = \frac{w_{ij} - \bar{w}_j}{\sigma_j} \quad \text{for } i = 1, \dots, N_0 \text{ and } j = 1, \dots, n \quad (12)$$

w_{ij} denotes the j th feature of the i th feature vector, N_0 is the number of the sample, and $\bar{w}_j$ and σ_j are the mean and standard deviation of the j th feature. The normalized features have zero mean and a standard deviation equal to one.

The key idea of the feature selection is to select a subset of m features ($m < n$) that leads to the smallest classification error. The selected m features are arranged in a new w -vector $\mathbf{z} = [z_1 \dots z_m]^T$. The selection of the features can be done using *sequential forward selection*.^[31] This method selects the best single feature and then adds one feature at a time that, in combination with the selected features, maximizes classification performance. The iteration is stopped once no considerable improvement in the performance is achieved on adding a new feature. By evaluating selection performance we ensure: (a) a small intraclass variation, and (b) a large interclass variation in the space of the selected features. For the first condition the intraclass-covariance is used:

$$C_b = \sum_{k=1}^N p_k [\bar{\mathbf{z}}_k - \bar{\mathbf{z}}][\bar{\mathbf{z}}_k - \bar{\mathbf{z}}]^T \quad (13)$$

where N means the number of classes, p_k denotes the a priori probability of the k th class, $\bar{\mathbf{z}}_k$ and $\bar{\mathbf{z}}$ are the mean value of the k th class and the mean value of the selected features. For the second condition the interclass-covariance is used:

$$C_w = \sum_{k=1}^N p_k C_k \quad (14)$$

where the covariance matrix of the k th class is given by:

$$C_k = \frac{1}{L_k - 1} \sum_{j=1}^{L_k} [z_{kj} - \bar{\mathbf{z}}_k][z_{kj} - \bar{\mathbf{z}}_k]^T \quad (15)$$

with z_{kj} the j th selected feature vector of the k th class, L_k is the number of samples of the k th class. Selection performance can be evaluated using the spur criterion for the selected features $\mathbf{z}$:

$$J = \text{spur}(C_w^{-1} C_b) \quad (16)$$

The larger the objective function J , the higher the selection performance.

Classification

Once the proper features are selected, a classifier can be designed. Typically, the classifier assigns a feature vector z to one of the two classes: *regular structure* or *flaw*, that are assigned “0” and “1,” respectively. In statistical pattern recognition, classification is performed using the concept of similarity: patterns that are *similar* are assigned to the same class.^[31] Although this approach is very simple, a good metric defining the similarity must be established. Using a representative sample we can make a supervised classification finding a discriminant function $d(z)$ that provides us with information on how similar a feature vector z is to the feature vector of a class. Figure 21a shows the case for just one feature. Some of the most important classifiers in statistical pattern recognition are:

Linear Classifier: In which a linear or quadratic combination of the selected features is used for a polynomial expansion of the discriminant function $d(z)$. If $d(z) > 0$ then z is assigned to class “1,” otherwise to class “0.” Using a least-squares approach, function $d(z)$ can be estimated from an ideal known function $d^*(z)$, that has been obtained from the representative sample.^[4]

Threshold Classifier: The decision boundaries of class “1” define a hypercube in feature space, i.e., if the m features are located between decision thresholds ($z'_1 \leq z_1 \leq z''_1$ and $z'_m \leq z_m \leq z''_m$) then the feature vector is assigned to class “1.” The thresholds are chosen from the representative sample.^[32]

Nearest Neighbor Classifier: A mean value $\bar{z}_k$ of each class of the representative sample is calculated. A feature vector z is assigned to class “ k ” if the Euclidean distance $\|z - \bar{z}_k\|$ is minimal. The mean value $\bar{z}_k$ can be viewed as a template.^[32]

Mahalanobis Classifier: The Mahalanobis classifier employs the same concept as the nearest neighbor classifier. However, it uses a new distance metric called the “Mahalanobis distance.” The Mahalanobis distance between z and $\bar{z}_k$ is defined as:

$$d_k(z, \bar{z}_k) = [z - \bar{z}_k]^T C^{-1}_k [z - \bar{z}_k] \quad (17)$$

The Mahalanobis classifier takes into account errors associated with prediction measurements, such as noise, by using the feature covariance matrix to scale features according to their variances.^[33]

Bayes Classifier: The feature vector z is assigned to class “ k ” if the probability that z belongs to this class is maximal. This conditional probability can be expressed as:

$$p(k|z) = \frac{p(z|k)p_k}{p(z)} \quad (18)$$

where $p(z|k)$ denotes the conditional probability of observing feature vector z given class “ k ,” $p(z)$ means the probability that feature vector z will be observed given no knowledge about the class, and p_k is the probability of occurrence of class “ k .”^[32,33]

The effectiveness of the classification can be measured in terms of *false positive* or *false negative* errors. False positive errors refer to cases where a segmented region is assigned to class “defect” when it is a regular structure, and false negative errors refer to undetected defects. Ideally, both should be zero.

Defining S_0 and S_1 as the number of regular structures (class “0”) and real flaws (class “1”) existing in the sample, after classification we have the situation where the regular S_0 structures are classified as S_{00} regular structures and S_{01}

Fig. 21 Classification: (a) distribution of the classes using one feature, (b) table of classification performance, (c) receiver operation curve

defects, i.e., $S_0 = S_{00} + S_{01}$. Similarly, the existing S_1 flaws are classified as S_{10} regular structures and S_{11} defects, i.e., $S_1 = S_{10} + S_{11}$ (see Fig. 21b).

S_{01} and S_{10} correspond to false positive and false negative errors, respectively. Such concepts are also referred to in literature as the *false acceptance rate (FAR)* and *false rejected rate (FRR)*, defined as $FAR = S_{01}/S_0$ and $FRR = S_{10}/S_1$. A classification can be tuned to a desired value of FAR . However, by decreasing the FAR of the system, the FRR would increase and vice versa. The *receiver operation curve (ROC)*, illustrated in Fig. 21c, is a plot of FAR vs. FRR which facilitates an assessment of recognition system performance at various operating points.^[31]

Flaw Simulation

A good way of assessing the performance of a method for inspecting castings is to examine simulated data. This evaluation allows one the possibility of tuning the parameters of the inspection method and of testing how well the method works in critical cases.

The nondestructive testing and evaluation community use three approaches to produce this simulated data:^[34]

- Mask superimposition onto real x-ray images.
- CAD models for castings and flaws.
- CAD models for flaws only and superimposition onto real x-ray images.

Mask Superimposition

The first technique attempts to simulate flaws by superimposing masks with different gray values onto real x-ray images.^[5,6,35] This approach is quite simple, as it neither requires a complex 3D model of the object under test nor of the flaw. It also provides a real x-ray image with real disturbances, albeit with simulated flaws.

Fig. 22 Flaw simulation using (a) square, (b) circle, and (c) Gaussian masks

In this technique, the original gray value I_0 of a pixel (u, v) of an x-ray image is altered by:

$$I_n(u, v) = I_0(u, v)(1 + M(u - u_0, v - v_0)) \quad (19)$$

with $I_n(u, v)$ the new grey value and M the mask that is centered in pixel (u_0, v_0) , where $M(i, j)$ is defined in the interval $-n/2 \leq i \leq n/2$ and $-m/2 \leq j \leq m/2$. Three typical masks are shown in Fig. 22. The Gaussian mask achieves the best simulation.

CAD Models for Casting and Flaw

The second approach simulates the entire x-ray imaging process.^[36,37] In this approach, characteristics of the x-ray source, the geometry, and material properties of objects and their defects, as well as the imaging process itself, are modeled and simulated independently. Complex objects and defect shapes can be simulated using CAD models.

The principle of the simulation is shown in Fig. 23. The x-ray may intersect different parts of the object. The intersection points between the modeled object with the corresponding x-ray beam that is projected into pixel (u, v) are calculated for each pixel (u, v) of the simulated image.

X-ray attenuation law forms the basis of this simulation approach.^[38]

Fig. 23 X-ray image simulation using CAD models

$$\varphi = \varphi_0 \exp(-\mu x) \quad (20)$$

where φ_0 is the incident radiation intensity, φ the transmitted intensity, x the thickness of the object under test, and μ the energy dependent linear attenuation coefficient associated with the material. According to attenuation law, the gray value of a pixel of the simulated image can be computed as:

$$I = A\varphi_0(E)\Delta\Omega \exp\left(-\sum_i \mu_i(E)x_i\right) + B \quad (21)$$

where A and B are linear parameters of I , $\varphi_0(E)$ is the incident radiation intensity with energy E , $\Delta\Omega$ is the solid angle that corresponds to the pixel observed from the source point, $\mu_i(E)$ designates the attenuation coefficient associated with the material i at the energy E , and x_i the total path length through the material i . Since the x-ray source is modeled as a raster of point sources, rays from every source point are traced to all pixels of the simulated image.

A flaw, such as a cavity, can be simulated as a material with no absorption. In Fig. 4 this simulation is shown schematically. An x-ray beam penetrates an object which has a cavity with thickness d . In this case, from Eq. 20 the transmitted radiation φ_d is given by:

$$\varphi_d = \varphi(x-d) = \varphi_0 \exp(-\mu(x-d)) = \varphi(x) \exp(\mu d) \quad (22)$$

where we assume that the absorption coefficient of the cavity is zero. If the flaw is an incrustated material, its absorption coefficient μ_d must be considered in Eq. 22:

$$\varphi_d = \varphi_0 \exp(-\mu(x-d)) \exp(-\mu_d d) = \varphi(x) \exp(d(\mu - \mu_d)) \quad (23)$$

Some complicated 3D flaw shapes are reported in Ref. [36]. The defect model is coupled with a CAD interface yielding 3D triangulated objects. Other kinds of flaws like cracks can also be obtained using this simulation technique.

Although this approach offers excellent flexibility for the setting of the objects and flaws to be tested, it has three disadvantages to the evaluation of the inspection methods' performance: (a) the x-ray image of the object under test is simulated (it would be better if we could count on real images with simulated flaws); (b) the simulation approach is only available when using a sophisticated computer package; (c) the computing time is expensive.

CAD Models for Flaws Only

This approach simulates only the flaws and not the whole x-ray image of the object under test.^[39] This method can be viewed as an improvement of the first-mentioned technique (Section 2.6.1) and the 3D modeling for the flaws

of the second one (Section 2.6.2). In this approach, a 3D modeled flaw is projected and superimposed onto real x-ray images of a homogeneous object according to the exponential attenuation law for x-rays (Eq. 20).

The gray value I registered by the CCD-camera can be expressed as a linear function of the transmitted radiation φ :

$$I(x) = A\varphi(x) + B \quad (24)$$

where A and B are the linear parameters of I , and x the thickness of the object under test. If the penetrated object has a cavity with thickness d as shown in Fig. 4 the transmitted radiation is given by Eq. 22. In this case the gray value registered by the CCD camera is calculated then from Eq. 24 as:

$$I(x-d) = A\varphi(x) \exp(\mu d) + B \quad (25)$$

Substituting the value of $A\varphi(x)$ from Eq. 24 we see that Eq. 25 may be written as:

$$I(x-d) = (I(x) - B) \exp(\mu d) + B \quad (26)$$

Parameter B can be estimated as follows: the maximal gray value $I_{\max}$ in an x-ray image is obtained when the thickness is zero. Additionally, the minimal gray value $I_{\min}$ is obtained when the thickness is $x_{\max}$. Substituting these values in Eq. 24, it yields:

$$\begin{cases} I_{\max} = A\varphi_0 + B \\ I_{\min} = A\varphi_0 \exp(-\mu x_{\max}) + B \end{cases}$$

From these equations, we may compute the value for B :

$$B = I_{\max} - \frac{\Delta I}{1 - \exp(-\mu x_{\max})} \quad (27)$$

where $\Delta I = I_{\max} - I_{\min}$. Usually, $I_{\max}$ and $I_{\min}$ are 255 and 0 respectively.

Using Eq. 26, we can alter the original gray value of the x-ray image $I(x)$ to simulate a new image $I(x-d)$ with a flaw. A 3D flaw can be modeled, projected, and superimposed onto a real x-ray image. The new gray value of a pixel, where the 3D flaw is projected, depends on four parameters: (a) the original gray value $I(x)$; (b) the linear absorption coefficient of the examined material μ ; (c) the maximal thickness observable in the x-ray image $x_{\max}$; and (d) the length of the intersection of the 3D flaw with the modeled x-ray beam d , that is projected into the pixel. In Ref. [39] an ellipsoidal model for a flaw is described in detail. Using this tool a simulation of an ellipsoidal flaw of any size and orientation can be made anywhere in the casting. This model can be used for flaws like blow-holes and other round defects. Two examples are shown in Fig. 24. The simulated flaws appear to be real due to

Fig. 24 Simulated ellipsoidal flaws using the third technique

the irregularity of the gray values. Other complex defect shapes can be simulated using CAD models.

This technique presents two advantages: simulation is better than with the first technique; and with respect to the second, this technique is faster given the reduced computational complexity. However, the model used in this method has four simplifications that were not presumed in the second simulation technique: (a) the x-ray source is assumed as a source point; (b) there is no consideration of noise in the model; (c) there is no consideration of the solid angle $\Delta\Omega$ of the x-ray beam that is projected onto a pixel; and (d) the spectrum of the radiation source is monochromatic.

DEFECT DETECTION IN CASTINGS: STATE OF THE ART

In this section different methods for the automated recognition of casting defects using image processing will be presented. These methods have been described in the literature within the past eighteen years and are considered to be the state of the art in this field. One can see that the approaches to detecting can be grouped into three groups:^[3]

1. Approaches where a filtering adapted to the structure is performed, which will be described in Section 3.1.
2. Approaches using pattern recognition, expert systems, artificial neural networks, general filters, or multiple view analyses to make them independent of the position and structure of the test piece, as described in Section 3.2.

3. Approaches using computer tomography to make a reconstruction of the cast piece and thereby detect defects, as described in Section 3.3

Reference Methods

In reference methods it is necessary to take still images at selected programmed inspection positions. A test image is then compared with the reference image. If a significant difference is identified, the test piece is classified as defective. In order to use a stored reference image (golden image), the distribution of gray values in the image must correlate to the current image. This makes a very precise positioning of the piece as well as very strict fabrication tolerances and the reproducibility of the x-ray parameters during imaging indispensable. Small variations in these variables lead to great differences between the two images. An alternative approach was suggested by Klatte (1985), whereby the reference image is calculated by filtering directly from the test image.^[40]

A schematic block diagram for this detection method for the automated recognition of die casting defects is presented in Fig. 25. To reduce the noise level, multiple images taken in a short period of time are averaged (integration) for each programmed position. As shown in Section 2.2.1, to build an arithmetic mean a signal to noise ratio is reached which is proportional to $\sqrt{n}$ with n resulting from the number of images added together. At first, a defect-free image y is estimated from each integrated x-ray image x using a filter. In this method each test position p has a filter (filter_p) which consists of several small masks.

Fig. 25 Reference method for automated detection of casting defects

Fig. 26 Interactive method for mask selection in a MODAN-Filter

The size of these masks and the values for their coefficients should be chosen so that the projected structure of the test piece at position p coincides with the masks' distribution. After this, an error difference image x/y is calculated. Casting defects are then detected when a sufficiently large difference between x-ray image and reference image occurs. The result of the binary segmentation is shown as e in Fig. 25.

The MODAN-Filter

The modified median filter, *MODAN-Filter*, was developed by Heinrich in the 1980s to detect casting defects automatically.^[5,6,41] With the MODAN-Filter it is possible to differentiate regular structures of the casting piece from casting defects.

The MODAN-Filter is a median filter with adapted filter masks. As explained in Section 2.3.1, a median filter is a ranking operator where the output value is the middle value of the input values ordered in a rising sequence. If the background captured by the median filter is constant, it is possible that structures in the foreground will be suppressed if the number of values belonging to the structure is less than one half of the input value to the filter. This characteristic is utilized to suppress the defect structures and to preserve the design features of the test piece in the image.

The goal of the background image function, thus, is to create a defect-free image from the test image. When calculating the background image function, the MODAN-Filter is used in order to suppress only the casting defect structures in the test image. Locally variable masks are used during MODAN-Filtering by adapting the form and size of the median filter masks to the design structure of the test piece. This way, the design structure is maintained in the test image (and the defects are suppressed). Additionally, the number of elements in the operator are reduced in order to optimize the computing time by not assigning all positions in the mask (sparsely populated median filter).^[12]

Different filter masks are suggested by Heinrich.^[6] He has developed automatic and interactive procedures for selecting the MODAN-Filter masks which takes the adaptation to the test piece structure into account. In both procedures the testing positions are chosen manually to ensure that every volume element of the cast piece is inspected. In the automatic procedure the mask is selected for each pixel, which minimizes an objective function for the segment of the test piece. Heinrich suggests the following objective function:

$$Q_{ij}(d, e) = Q_{ij}^d(d, e) + Q_{ij}^s(d, e) + Q_{ij}^m(d, e) \quad (28)$$

The coordinates of the pixel are given by (i, j) , and (d, e) represent the height and width of the mask. Q^d , Q^s , and Q^m denote the detection defects, spurious reading,* and the mask matrix size, respectively. The error-free reference image is estimated for the three input values as follows:

$$y(i, j) = \text{median}(x_1, x_2, x_3) \quad (29)$$

with

$$\begin{aligned} x_1 &= x(i, j) \\ x_2 &= x(i + d_{ij}, j + e_{ij}) \\ x_3 &= x(i - d_{ij}, j - e_{ij}) \end{aligned}$$

where $y(i, j)$ are the gray values in the reference image and $x(i, j)$ in the test image at pixel (i, j) . The filter direction of the masks is determined by the distances d_{ij} and e_{ij} . Casting defects are detected when

$$|y(i, j) - x(i, j)| > \theta_{ij} \quad (30)$$

This makes it possible to create a good adaptation to the structure of the piece; however, a greater data storage capacity is needed because of the different filter masks used for each pixel. The storage requirements can be reduced in the interactive procedure by choosing the same mask for all rectangular areas in the interactive procedure. This means that

$$\begin{aligned} d_{ij} &= d_k & e_{ij} &= e_k & \text{for } i_k^0 \leq i \leq i_k^1 & j_k^0 \leq j \leq j_k^1 \end{aligned} \quad (31)$$

where i_k^0 , i_k^1 , j_k^0 , and j_k^1 define the boundaries of the k th rectangular mask. The adaptation to the structure is not as exact in this case as in the first procedure.

The interactive procedure is shown in Fig. 26: for every testing position masks with horizontal, vertical, and both diagonal filter directions are tested for spurious readings as compared to a defect-free casting. In this step it is decided which direction will not be applied. Next, the objective function (Eq. 28) is rated in order to select the best mask.

*For three input values of the MODAN-Filter (x_1, x_2, x_3) the detection error and spurious reading is defined as $|x_2 - x_1| + |x_2 - x_3|$ and $x_2 - \text{median}(x_1, x_2, x_3)$ respectively.^[6]

Fig. 27 Automatic mask selection for MODAN-Filter and detection^[42]

Source: With permission.

The filter masks are to be selected so that variations of the regular structures in the test piece do not lead to spurious readings. Finally, individual filter sectors are combined.

Hecker proposes a method in Ref. [42] for the automatic adaptation of the masks to the regular structures of the test piece. For the correct choice of a mask it is necessary to satisfy two criteria: (a) the appropriate gray values for the structure in the mask must be constant, and (b) the size of the mask must be at least twice as large as in the extent of the casting defect to be found. To fulfill the first criterion, the mask direction is chosen to be perpendicular to the direction of the gradient of the piece's contour. The size of the mask is chosen according to the testing specifications for the extent of the expected casting defect. The method is shown in Fig. 27 (compare with Fig. 25). Only four directions of the gradient are applied: $[0^\circ-180^\circ]$, $[45^\circ-225^\circ]$, $[90^\circ-270^\circ]$, and $[135^\circ-315^\circ]$, which are shown as four different gray values in Fig. 8. The method generates rectangular regions as appropriate test regions, which have masks with identical directions and sizes.

In Ref. [35] Hecker improved the automatic parameterization of the MODAN-Filter. The method which he calls optimized MODAN-Filtering allocates to each pixel the mask from a mask pool which gives the smallest *amplitude error*. For this search, representative piece images are used which were taken of the same piece at the same position. The amplitude error is described by Hecker as the difference between the true expanse of the error depth from the detected value. The pool mentioned above includes 128 different masks with three input values. The masks are

distributed among sixteen different mask sizes (16, 17, ..., 31 pixels) along eight different directions ($[0^\circ-180^\circ]$, $[22.5^\circ-202.5^\circ]$, ..., $[157.5^\circ-337.5^\circ]$).

Signal Synchronized Filter

Hecker developed the *signal synchronized filter* in Ref. [35] to calculate the background image function. This method generalizes the equation used for the MODAN-Filter (Fig. 26):

$$y(i, j) = \text{median}[x(i, j), x(i + d_{ij1}, j + e_{ij1}), \dots, x(i + d_{ijn_s}, j + e_{ijn_s})] \quad (32)$$

where the filter parameters (d_{ijk}, e_{ijk}) are chosen so that the objective function

$$Q_{ijk}(d_{ijk}, e_{ijk}) = \sum_{m=1}^{N_R} [x_m(i, j) - x_m(i + d_{ijk}, j + e_{ijk})]^2 \quad (33)$$

is minimized when the condition $(d_{ijk}, e_{ijk}) \neq (dl, e_{ijl})$ and $d_{ijk}, e_{ijk} > \tau_{\min}$ for $k, l = 1, \dots, n_s$ with $k \neq l$. The objective function considers N_r representative piece images $\{x_1\}, \dots, \{x_{N_R}\}$, which were obtained from the same cast piece and same position. During the experiments only three input values ($n_s = 2$) are processed (see Fig. 28). In order to determine the parameters, the number of representative piece images reportedly required is $20 \leq N_r \leq 30$. Beyond this, Hecker

Fig. 28 Weighted synchronized filtering (for unweighted filters $a_{ijk} = 1$ and $b_{ijk} = 0$)

developed the *weighted median operator*, in which the input value $x(i + d_{ijk}, j + e_{ijk})$ is entered via

$$a_{ijk} \cdot x(i + d_{ijk}, j + e_{ijk}) + b_{ijk}$$

in Eq. 32 for $k = 1, \dots, n_s$. For the case of the weighted median operator, the objective function is:

$$Q_{ijk}(a_{ijk}, b_{ijk}, d_{ijk}, e_{ijk}) = \sum_{m=1}^{N_R} [A - a_{ijk}B + b_{ijk}]^2 \quad (34)$$

with:

$$\begin{aligned} A &= x_m(i, j) \\ B &= x_m(i + d_{ijk}, j + e_{ijk}) \end{aligned}$$

Once (d_{ijk}, e_{ijk}) are identified in Eq. 34, one can calculate the coefficients (a_{ijk}, b_{ijk}) to minimize the objective function by linear regression:

$$\begin{aligned} a_{ijk} &= \frac{N_R \sum AB - \sum A \sum B}{N_R \sum B^2 - (\sum B)^2} \\ b_{ijk} &= \frac{\sum A \sum B^2 - \sum AB \sum B}{N_R \sum B^2 - (\sum B)^2} \end{aligned} \quad (35)$$

with summations from $m = 1$ to $m = N_r$. Since the coefficients (a_{ijk}, b_{ijk}) are dependent on d_{ijk} and e_{ijk} , the optimization problem can be formulated, so that the objective function is only a function of the distance parameter (d_{ijk}, e_{ijk}) .

As the absolute minimum of the objective function is found by searching, the determination of the filter parameters presents an enormous computational effort. To parameterize the filter at N positions of the test piece, N_r representative piece images per position, and $N_i \times N_j$ pixels per image one requires $NN_i^2 N_j^2 N_r$ comparative

operations. When using the weighted median operator, another $8 + 2N_r$ multiplications and $3 + 3N_r$ summations must be performed for each comparison to determine the parameters a and b in Eq. 35. Typically, the search for optimal parameters for a test piece takes several weeks. To reduce the computing time Hecker recommends, among other things, that the reference images be subsampled and the reference area be limited where the optimal distance between d and e are sought. Obviously, there must be a compromise between the reduction of computing time and the robustness of the detection. For this reason the reduced computing time required for a robust detection is not yet acceptable for industrial application.

The PXV 5000 Radioscopic Test System

The radioscopic test system PXV 5000 was developed in the early 1990s by Philips Industrial X-ray GmbH as a fully automatic radioscopic testing device.^[1,43] The system was further developed by YXLON International X-ray GmbH.*

The testing system evaluates a random sample of a defect-free test piece in a learning process. Every structure and every irregularity that the system finds in the test piece is classified as a regular structure and entered into an appropriate library.^[44] The essential steps in the PXV 5000 system (see block diagram in Fig. 29) are discussed below:^[2]

Integration: To suppress the noise level, depending on the application, 4 to 16 x-ray images are integrated at the same test piece position.

Filtering: The PXV 5000 makes the application of up to eight processing steps per position, in which different filters can be selected from a long list of filter algorithms and masks which can be combined freely. In this way, a defect-free x-ray image can be identified in the test image.

*The company YXLON International X-ray GmbH was created in 1997 from the German company Philips X-ray GmbH and the Danish company Andrex GmbH.

Fig. 29 Block diagram of the detection approach used in the PXV 5000

A difference image is generated from the comparison of both images.*

Masking: In this step, all irrelevant structures are removed which are located outside of a freely definable mask.

Segmentation: Using a two-threshold procedure, potential defect structures are segmented. The higher threshold value serves to detect the potential defect and the lower to detect the projected size in the image.

Feature extraction: Features are extracted (e.g., center, area, perimeter, Feret coordinates,** measure of compactness, extent, minimum, maximum, and average gray level value) from the segments which describe their properties.

Matching and classification: By comparison of the model's features from which they were extracted during the learning process and stored in a library, it is possible to eliminate the regular structures of the piece.

According to YXLON, only three defects were detected during the inspection of 600 aluminum die cast pieces. Furthermore, all casting defects larger than 1.56 mm^2 were detected.

Radioscopic Testing System SABA 2000T

The fully automatic radioscopic examination device Seifert Automatic Image Evaluation (SABA) was developed in the late 1980s by the company Rich. Seifert & Co.^[47] Continual improvements in mechanical drives and computer speeds by Seifert made it possible to develop the radioscopic examination device SABA-2000 in the year 1994^[48] and the SABA-2000T in 1998,^[49] which reached higher digital image resolutions and faster testing speeds. According to the Seifert company, as reported in Ref. [34], the detection approach used in the SABA series has remained unchanged, as it is based on an optimization of the MODAN-Filter (see Section 2.1), as developed in the 1980s for the approximation of a defect-free x-ray image. The detection of casting defects is performed as in Fig. 25. This testing system determined only two deviations during the inspection with 1034 concurring decisions.^[47,50]

*A new filtering approach - called AI (Automatic Inspector) - based on neural networks has been recently developed by YXLON.^[45,46]

**Coordinates of the lower left corner and upper right corner for the smallest rectangle circumscribing the segment.

Methods without *a priori* Knowledge

Methods will be described in this section which can detect casting defects in a test piece without prior knowledge of the piece's structure.

ISAR Radioscopic Testing System

The *Intelligent System for Automated Radioscopic testing* (ISAR) was developed by the Fraunhofer Institute for Integrated Circuits (IIS-A) in the 1990s.^[51,52] Inspection is performed with the aid of a COMMED-Filter (*COMBined MEDianfilter*), also developed by the Fraunhofer Institute.

The die cast pieces are identified by the system, so that an examination specifically for that piece can be performed. After the die cast piece is identified, x-ray parameters, testing criteria, translocation of the handling device, and inspection positions are selected.

According to IIS-A, the COMMED-Filter can detect casting defects without *a priori* knowledge of the test piece structure. The algorithm can differentiate between the structure of the test piece (edges, corners, bore holes, etc.) and structures which are not part of the piece. During the testing of wheel rims, for example, the time for image analysis for an aluminum wheel with a diameter of 17" was about 35 sec for the required 25 different positions.

Gayer et al.'s Method

This method for defect detection was originally published in 1990 by Gayer et al. for the testing of welding seams.^[53] But the algorithm can also be used for the recognition of casting defects. The proposed method can be summarized as having two steps:

1. A quick search for potential defects in the x-ray image: assuming that the defects will be smaller than the regular structure of the test piece, potential defects are classified as those regions of the image where higher frequencies are significant. The spectrum of the x-ray image is determined with the help of a fast Fourier transformation, which is calculated either row by row or column by column in little 32×32 windows. When the sum of the higher frequencies of a window is greater than a given threshold value, the entire window is marked as potentially

defective. Another possibility is suggested by the authors as part of this task: a window is selected as potentially defective when the sum of the first derivative of the rows and columns of a window is large enough.

2. Identification and location of the true defect: because of the time consuming nature of this step, only those regions which were previously classified as being potentially defective are studied here. Two algorithms were developed here as well. The first leads to a matching* between the potential defect and typical defects which are stored in a library as templates. Whenever a large resemblance between the potential defect and a template is found, the potential defect is classified as a true defect. The second algorithm estimates a defect-free x-ray image of the test piece by modeling every line of an interpolated spline function without special consideration for the potentially defective region. Following this, the original and the defect-free images are compared. True defects are identified when large differences occur compared to the original input image.

Kehoe and Parker's Method

In 1992 Kehoe and Parker presented in Ref. [54] an intelligent, knowledge-based casting defect detection which utilizes an image processor and an expert system to automatically recognize die casting defects. The method consists essentially of two steps:

Detection and Analysis: At first, possible defects are segmented in small regions by adaptive thresholding.^[30] Then the detected possible defects are fused by dilation and erosion (*closing*).^[12] Finally, geometric characteristics are extracted from the fused regions.

Classification: By using an expert system the regions are segregated into defect classes, e.g., bubbles, slack, cracks, etc.

This system was investigated in the laboratory with eight x-ray images and compared with visual detection. The automated detector was able to identify more defects than human operators could find. The difficulty with this method lies in the creation of a knowledge data bank which includes all possible defects.

Boerner and Strecker's Method

At the end of the 1980s Boerner and Strecker presented in Ref. [4] a method for the automated casting defect recognition which they had developed on their own at the Philips Research Laboratory in Hamburg. As usual, the method is centered on the analysis of individual x-ray images taken at the desired position of the test piece. After improving the

image quality with a look-up-table^[12] and shading correction (see Section 2.2.3), the procedure extracts the feature to be segmented in every pixel of the x-ray image.

A classifier is designed to segregate every pixel (i, j) into class k . There are typically only two classes: the class $k = 1$ for a regular structure of the piece and the class $k = 2$ for defects. In general, the method is valid for N_k classes.

With the help of a decision function, the image's pixels are classified. The decision functions are calculated as linear functions with the features:

$$d_k(i, j) = a_{k0} + \sum_{p=1}^n a_{kp} z_p(i, j) \quad (36)$$

or as quadratic functions with the features

$$d_k(i, j) = a_{k0} + \sum_{p=1}^n a_{kp} z_p(i, j) + \sum_{p=1}^n \sum_{q=p}^n a_{k,p,q} z_p(i, j) z_q(i, j) \quad (37)$$

for $k = 1, \dots, N_k$. Here $z_p(i, j)$ are the values of the p th extracted feature of the pixel (i, j) for $p = 1, \dots, n$ and $a_{k0}, a_{k1}, \dots$ are the linear parameters in the decision function. Using a linear regression, these parameters are determined in a learning phase by minimization of the quadratic distance between $d_k(i, j)$ and the idealized decision function $d_k^*(i, j)$. The function $d_k^*(i, j)$ is determined manually out of a random learning sample and assumes the value of 1 or 0 depending on whether the pixel (i, j) belongs to class k or not.

Once the classifier has been learned, a pixel (i, j) in a test image is placed in class k when $d_k(i, j) \geq d_k^*(i, j) > \theta_k$, for $k' = 1, \dots, N_k$ where θ_k is the threshold value for the p th class.

Following this, the defective neighboring pixels are combined to build regions. Finally, a region is detected as being defective if it has a circular form and covers a large enough area.

Boerner and Strecker suggested that the difference between the original image and its image filtered by a DoG** or median methods and the rotation invariant *Zernike* feature be named pixel features. The latter designates the use of the gray value of the pixel relative to its surroundings developed in a series of Zernike polynomials.^[56] According to the authors, 92% of all defects were recognized with less than 4% false detection in an inspection of 200 die cast pieces. However, the method can only detect circular defects.

Lawson and Parker's Method

In 1994 Lawson and Parker proposed in Ref. [57] that artificial neural networks (ANN) be used for the automated

*Matching is performed with a Sequential Similarity Detection method.

**The DoG (Difference of Gaussians) filter is calculated as the difference between two Gauss filters. This filtration corresponds to a band pass filter.^[12,55]

detection of defects in x-ray images. The method generates a binary image from the test image where each pixel is either 0 when a regular structure feature of the piece or 1 when a defect is detected. This entails the supervised learning of a multi-layer perceptron network (MLP) where the attempt is made to obtain a detection from training data. A back propagation algorithm is used for the assignment of weightings within the MLP.^[58]

The authors use one of two hidden layers in the network topography of the ANN, where the input signal corresponds to a window of $m \times m$ gray values in the x-ray image. The output signal is the pixel at the image center in the binary image. Since the threshold value function for the neurons are sigmoidal in this method, a threshold is used to obtain a binary output signal.

The two hidden layers each have ten cells. During the investigation it was determined that the size of the window for the input signal must be larger than 7×7 ($m > 7$), otherwise, convergence will not be obtained in the learning phase. A group of 50,000 randomly chosen windows were used as the basis of the training data.

The desired detection in the training data was obtained with a segmenting procedure based on an adaptive threshold. During the experiments of five x-ray images, Lawson and Parker show that the detection using ANN is superior to the segmenting method using adapted thresholds. The defects were found successfully and there were no false detections.

Mery and Filbert's Method

A new method for the automated inspection of aluminum die cast pieces with the aid of monocular x-ray image sequences was presented recently by Mery and Filbert.^[21,22,59] The procedure is able to perform casting defect recognition in two stages with a single filter and without a priori knowledge of the test piece structure automatically.

In the first step, an edge detection procedure based on the Laplacian-of-Gaussian is employed to find abrupt changes in gray values (edges) in every x-ray image. Here, the zero crossings of the second derivative of the Gauss low-pass filtered image are detected.^[12] These edges are then utilized to search for regions with a certain area and a high contrast level compared to their surroundings,* as shown in Section 2.3.2.

In the second step, the attempt is made to track the hypothetical casting defects in the sequence of images. False detections can be eliminated successfully in this manner, since they do not appear in the following images and, thus, cannot be tracked. In contrast, the true casting defects in the image sequence can be tracked successfully

because they are located in the position dictated by the geometric conditions.

The tracking of the hypothetical casting defects in the image sequence is performed according to the principle of multiple view analysis.^[60-62] Multi-focal tensors are applied to reduce the computation time. Following a 3D reconstruction of the position of the hypothetical casting defect tracked in the image sequence, it is possible to eliminate those which do not lie within the boundaries of the test piece.

The elements of this method were tested in a laboratory prototype on real and simulated cases and the preliminary results of detection experiments are promising (100% of all casting defects recognized in 16 image sequences with no false detections). Above and beyond this, the required computing time is acceptable for practical applications. As the performance of this method has only been tested on a limited number of image sequences, it will be necessary to analyze a broader databank.

Industrial Computer Tomography

Another method for the automated detection of casting defects is the (x-ray) computer tomography, which also analyzes the weakening of x-rays as they pass through an object. In contrast to radioscopic testing, two-dimensional computer tomography produces a cross-section of the test piece**: two-dimensional images of a flat slice through the investigated object are created out of one-dimensional projections. The projections show the profiles of x-rays weakened by the object, which are measured as a function angularly dependent of the absorption. The emitter must be led around the object in the plane of interest (or the object is rotated) to obtain measurements at different angular positions. This differentiates computer tomography from traditional radioscopic techniques, where the irradiated image is a two-dimensional projection of the object under investigation. The structures contained in the plane of radiation at different depths within the object can be displayed in the cross-sectional image of the computer tomographic reconstruction without overlap (see Fig. 30).

For the calculation of the object's cross-sectional plane from the measured projections, a great number of algorithms are available which can be classified in general as transformation methods or series development approaches. The methods used in nondestructive materials testing typically belong to the transformation methods. These are based on the projection slice theorem, which states that a one-dimensional Fourier transformation of a projection P_θ at the angle θ is equal to

*Other methods for segmenting hypothetical casting defects, such as in the PXV 5000 (see Section 16.3.1.3), could be used in this first step.^[2]

**The word "tomography" is derived from the Greek words $\tau\omicron\mu\omicron\varsigma$ and $graphos$ and is equivalent to cross-sectional image. The term "computer" corresponds more directly to computation than computer as such.

Fig. 30 Comparison between a conventional x-ray image and the result of a computer tomographic reconstruction

Fig. 31 Projection slice theorem

the two-dimensional Fourier transformation of the object function along a straight line through the origin in Fourier coordinates at the angle θ ^[63,64] (see Fig. 31). The projection P_θ as a function $f(x, y)$ here at the angle θ is designated as the entirety of all line integrals of this angle. A line integral P_θ along a straight line l from A to B is defined as

$$p_\theta(r) = \int_l f(x, y) ds \quad (38)$$

where $f(x, y)$ describes the two-dimensional distribution of the x-ray absorption coefficient in the cross-section of the irradiated object, and the straight line/describes the path of a single monoenergetic x-ray beam from the x-ray source through the object to the detector element. The x-ray beam is weakened according to the corresponding law of radiation absorption:

$$I = I_0 \exp \left(- \int_l \mu(x, y) ds \right) \quad (39)$$

where $\mu(x, y)$ describes the two-dimensional distribution of the x-ray absorption coefficient which corresponds to the image function $f(x, y)$. In Eq. 39 I_0 stands for the radiation emitted from the x-ray source and I is the radiation incident on the detector after being weakened by the object. After rearranging Eq. 39, the value measured at the detector results:

$$p_\theta = \ln \left(\frac{I_0}{I} \right) = \int_l \mu(x, y) ds \quad (40)$$

A projection P_θ at the angle θ is obtained through realization of a parallel beam geometry, e.g., by shifting the radiation emitter-detector arrangement radially after each measurement. The reconstruction of the object function $f(x, y)$ from its projections presents a typical inverse problem.^[65]

In practice, however, these ideal conditions cannot be realized.^[66] Only a limited number of projection measurements are available for reconstruction, and these are generated from a limited number of line integrals. And thus, a two-dimensional function cannot be uniquely defined.

Different image functions can always be created which possess the same projection.

For three-dimensional computer tomography, methods are used which analyze two-dimensional projections.* Feldkamp describes a mathematical method in Ref. [67] for the calculation of three-dimensional results with a cone beam projection. Other methods adhere to another approach, whereby the results of conventional 2D tomography are layered on top of each other according to their respective positions in the object and the values between the individual (reconstructed) object planes are interpolated.

Common to all of the methods using transformation is the use of filters with lowpass characteristics. This has a negative impact especially on the use in casting piece inspection, since great discontinuities in the measured values result from the object edges in the projections (highly absorptive material next to hollow spaces in the design). This leads to large artifacts, which can make image analysis impossible. In order to obtain high local resolution in the reconstructed object, it is desirable that the x-ray tube have as small a focal point as possible. In microfocus computer tomography (μ CT) resolutions on the order of a few mm are obtainable. To penetrate the aluminum die cast pieces with relevant material thickness for use in the automotive industry, a minimum energy level is needed which lies above the specifications of most microfocal tubes. The problem posed lies in the heat removal, which must occur rapidly enough that any possible damage to the tube is prevented.

Furthermore, computer tomography is a very time intensive process requiring a minimum measurement time for adequate signal to noise ratios as well as a minimum number of projections for the desired local resolution. As a result of the physical reasons which dictate that a minimum measurement time be given for each angular position, the only remaining way to reduce the measurement time is to reduce the number of measurement positions. In those cases where measurement data are lacking, one speaks of a "limited data problem".^[68] Apart from the reduced measurement time, it can be desirable in industrial applications to analyze only selected projections for reconstruction. Reasons for these selections may lie both in the difficulty in obtaining data for certain angular positions or regions and in the projections of certain objects which are unsuitable for analysis (e.g., polyvalent x-ray absorption properties, inadequate signal to noise ratio for all angular positions). No industrial applications are known to the authors for this area of "limited data problems." Research work is underway with different approaches to optimizing the computations as well as modifications to known algorithms.

*The problems founded in the principle of tomography persist: three-dimensional results also exhibit a dimension one higher than the projections which are analyzed (two-dimensional "images").

CONCLUSIONS

In this chapter, we have discussed the use of image processing as a tool in the automated detection of faults in aluminum castings. We also presented an overview of the theory of image processing that it normally entails.

Additionally, the fundamental principles of various methods for the automated detection of die casting defects have been explained. These methods have been published over the past eighteen years and plot industry and academic development of the sector.

The detection approaches were, roughly speaking, divided into three groups: reference methods, methods without a priori knowledge, and computer tomography.

Methods from the first group have become the most widely established in industrial applications owing to their high detection performance. Complicated filtering, which is tailored to the test piece, hinders these methods, however. Typically, this optimization process takes two or more weeks, depending on whether it is performed manually or automatically.

The existence of common properties that define all casting defects well and also differentiate them from design features of the test pieces are prerequisites for using methods from the second group. These prerequisites are often only fulfilled in special testing situations.

The industrial use of computer tomography for the inspection of die cast parts for the automotive industry is currently limited to materials research and development as well as to the inspection of especially important and expensive parts.^[69,70] Such systems require considerable time for measurements and economically priced systems also have insufficient resolution to detect small defects.

Intermetallics of Aluminum

Georg Frommeyer and Sven Knippscheer

Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany

Abstract

Aluminum-rich intermetallic compounds of the Al_3X -type with transition metals ($X = Ti, Zr, Nb, V$) of Groups IVb and Vb are of interest in the development of novel high-temperature and lightweight structural materials. This article describes the important physical and mechanical properties of trialuminides with DO_{22} structure and their $L1_2$ variations. Topical coverage includes: crystal structure and selected physical properties, plastic deformation, oxidation behavior, and applications.

Keywords: Aluminides; Crystal structure; Fracture; Microstructure; Plasticity.

INTRODUCTION

The aluminum-rich intermetallic compounds of the Al_3X -type with transition metals ($X = Ti, Zr, Nb, V$) of groups IVb and Vb are of interest in the development of novel high temperature and light weight structural materials. The Al_3X compounds of main interest are: Al_3Ti and Al_3Nb with ordered DO_{22} superlattice structure and some modified ones of the composition $(Al, X)_3Ti$ with $L1_2$ type of crystal structure. The important aspects of these aluminium-rich intermetallics are:

- Aluminium atoms are the main constituents of 75 at. %.
- The low density of less than 3.5 Mg m^{-3} (Al_3Ti).
- High elastic moduli and high melting points.

The first report on the deformation behaviour of this class of trialuminides appeared in 1974. The first paper on Al_3Nb was published by Shechtman and Jacobson in 1975.^[1] About 13 years later Yamaguchi et al.^[2] reported on deformation behaviour of Al_3Ti . These preliminary studies showed that Al_3Ti and Al_3Nb were brittle at room and medium temperature. Almost at the same time detailed studies revealed that specific twinning occurs in the DO_{22} crystal structure, which does not disturb the ordering. However, this deformation mechanism plays an important role and inspired many researchers to improve the low temperature ductility of these compounds. Three main approaches have been attempted. These are:

- Microalloying for refining the microstructure.
- Macroalloying to change the crystal structure into higher symmetry ($L1_2$) and to increase the number of the independent slip systems.
- Rapid solidification and powder metallurgical techniques including thermo-mechanical treatment.

The microalloying approach in combination with rapid solidification has been producing some promising results. A series of ternary and quaternary aluminides based on $(Al, X, Y)_3Ti$ with cubic $L1_2$ structure revealed some ductility in bending tests. However, the tetragonal DO_{22} and the modified cubic $L1_2$ Al_3Ti and Al_3Nb compounds are in general quite brittle for engineering applications. At higher temperatures above 700°C the modified trialuminides show sufficient ductility and strength properties for certain applications in internal combustion engines and in jet engines.

The present chapter describes the important physical and mechanical properties of trialuminides with DO_{22} structure and their $L1_2$ variations. Particular emphasis is made on deformation modes and dislocation structures, the effect of alloying on the mechanical and oxidation properties, and on the application potential. In addition to Al_3Ti relevant investigations on Al_3Nb , Al_3V , Al_3Zr and on cubic $(Al, X)_3Ti$ variations are reviewed. For specific properties the reader is referred to review articles published by Yamaguchi et al.^[3] regarding the deformation mechanism of Al_3Ti , by Yamaguchi and Umakoshi^[4] for lattice defects, by Georges et al.^[5] for deformation and the structure of $L1_2$ trialuminides, by Mikkola and Nic^[6] for alloying and cubic phase stability, by Morris^[7,8] for antiphase boundary (APB) faults, and by Reip and Sauthoff et al.^[9,10] for structure and properties of Al_3Nb .

STRUCTURE AND SELECTED PHYSICAL PROPERTIES

Crystal Structure

The ordered tetragonal DO_{22} structure is derived from the ordered face centered cubic $L1_2$ structure (Fig. 1a) by introducing an antiphase boundary (APB) with a displacement

Fig. 1 Elementary cells of the ordered $L1_2$, DO_{22} and DO_{23} structures

Table 1 Physical properties of DO_{22} -Trialuminides Al_3X

		Density ρ [Mg m ⁻³]	Linear thermal expansion coef. $\alpha \cdot 10^{-6}$, [K ⁻¹]	Spec. electrical resistance $\rho \cdot 10^{-8}$, [mΩ]
Melting temperature (K)				
Al_3Ti	1620	3.36	9.75–9.9	27
Al_3Nb	1880	4.54	9.6–9.8	49

vector of $\frac{1}{2}\langle 110 \rangle$ on every (001) plane (Fig. 1b). Al_3Ti and Al_3Nb crystallize into this $L1_2$ -derivative, long-period superlattice structure. The DO_{23} structure is formed by introducing the APB on every second (001) plane (Fig. 1c). Al_3Zr and Al_3Hf (at low temperatures), which are akin to Al_3Ti , possess this structure. The lattice parameters of Al_3Ti are $a = 0.3848$ nm and $c = 0.8596$ nm ($c/a = 2.23$), see e.g. Villars and Calvert.^[11] The density of Al_3Ti calculated from these lattice parameters is 3.36 Mg m⁻³. For Al_3Nb the lattice parameters are quite similar to those of Al_3Ti . In c-axis of the unit cell the lattice constant is $c = 0.8615$ nm and the value of $a = 0.3848$ nm. Considering the higher atomic weight of Niobium atoms the calculated density of Al_3Nb is about $4,454$ Mg m⁻³. This value is comparable with the density of pure Titanium.

Table 1 represents some important physical properties of polycrystalline Al_3Ti and Al_3Nb compounds.

Hardness and Elastic Properties

Vickers' macro hardness values and elastic moduli of Al_3Ti and Al_3Nb are presented in Table 2a. The elastic stiffness constants C_{ij} of Al_3Ti and of the constituents Ti and Al were determined by measurements of ultrasonic sound wave velocity in crystals of the compounds^[12] and presented in Table 2b. Values of Young's modulus (E), shear modulus (G), bulk modulus (K) and Poisson's ratio (ν) for the polycrystalline compound Al_3Ti were calculated from the stiffness constants. The elastic moduli and Poisson's ratio of Al_3Nb were determined by the resonance frequency method (Reip,^[13]). For comparison the corresponding elastic constants of Al_3Ti were calculated by Fu^[14] and Yoo and Fu.^[15] The calculated elastic constants are in reasonably good agreement with experimental values.

Table 2a Hardness and elastic properties

	Vickers' Hardness (HV ₁₀)	Young's Modulus E (GPa)	Shear Modulus G (GPa)	Poisson's ratio ν
Al ₃ Ti	390–420	166	90	0.16–0.19
Al ₃ Nb	565	246	105	0.17–0.19

Table 2b Stiffness and elastic constants of Al₃Ti and its constituent elements (10² GPa)

							Bulk moduli	Young's moduli	Shear moduli	Poisson's ratio	Specific moduli	
	C ₁₁	C ₃₃	C ₄₄	C ₆₆	C ₁₂	C ₁₃	K	E	G	ν	E/ ρ	G/ ρ
Al ₃ Ti _(exp.)	2.177	2.175	0.920	1.165	0.577	0.455	1.056	2.157	0.930	0.160	0.63	0.27
Al ₃ Ti _(theo.)	2.02	2.43	1.45	1.00	0.88	0.60	1.22	2.30	0.97	0.19	0.68	0.29
Al	1.082	C ₁₁	0.285	C ₄₄	0.613	C ₁₂	0.752	0.706	0.262	0.345	0.26	0.10
Ti	1.624	1.807	0.467	C ₄₄	0.920	0.690	1.084	1.202	0.456	0.361	0.27	0.10

Both, experimentally and theoretically determined elastic moduli E and G of Al₃Ti are approximately three and a half times those for pure aluminium and about two and a half times those of pure titanium, even though its primary constituent is aluminium and hence the density of Al₃Ti is only 24% higher than that of pure aluminium. The specific Young's and shear moduli of Al₃Ti are much higher than those of the constituent elements. The elastic stiffness constants of Al₃Zr, which is another example of a compound with an L₁₂-derivative, long-period structure, have also been measured by Nakamura and Kimura,^[12] and the values of E and G have also been found to be much higher than the corresponding values for aluminium. Thus, this seems to be characteristic of this class of trialuminides. In contrast, the bulk modulus of Al₃Ti is only 44% higher than that of pure aluminium. This is also the case for Al₃Nb. Thus, these trialuminides, in general, have smaller K/G ratios, which correlate with the tendency toward brittleness for the trialuminides since a high value of G implies a high critical stress for dislocation generation at the crack tip.

DISLOCATIONS, BURGERS VECTOR

The atomic arrangement and planar faults on closed packed (111) planes in an Al₃X compound with DO₂₂ structure is shown in Fig. 2. The periodic introduction of antiphase boundaries APB into the L₁₂ structure transforms the triangular arrangement of B atoms on (111) in the L₁₂ structure into a rectangular arrangement. From geometrical considerations, five possible planar faults have to be considered. These are the antiphase boundaries: APB-I, APB-II, the complex stacking faults: CSF-I, CSF-II and the superlattice intrinsic stacking fault: SISF. The stacking fault energies have been calculated by Yamaguchi and Umakoshi.^[4]

The SISF, which involves no first- and second-nearest neighbor wrong bonds, is expected to have generally

a much lower energy than the other possible faults on {111} such as APB and CSF. The displacement vector **b**_{Al} forms an APB also on (001) without creating first nearest neighbor wrong bonds. Its energy is given by:

$$E_{\text{APB-I}}^{(001)} = \frac{2V^{(2)}}{a^2} \quad (1)$$

For the DO₂₂ structure to be stable with respect to both the DO₂₃ and L₁₂ structures $E_{\text{APB-I}}^{(001)} > 0$ where $V^{(2)}$ is the second neighbour ordering energy. The energies of the five possible faults on {111} are thus generally expected to be in the following decreasing order:

$$E_{\text{CSF-I}} > E_{\text{CSF-II}} > E_{\text{APB-I}} > E_{\text{SISF}} \quad (2)$$

APB-I on (001) has a lower energy than CSF-I, CSF-II, APB-I and APB-II on {111}. The APB-I on (001) is always stable for obvious symmetry reasons, while the stability of the faults on {111} is not guaranteed on symmetry grounds Yamaguchi et al.^[16,17] They can be unstable.

The DO₂₂ structure exhibits relatively short lattice translation vectors along $\langle 110 \rangle$ and $\langle 112 \rangle$ on {111}, and along $\langle 110 \rangle$ and $\langle 100 \rangle$ on (001). These vectors are $\langle 110 \rangle$ (e.g. $2\mathbf{b}_{\text{Al}}$ in Fig. 2), $\frac{1}{2}\langle 112 \rangle$ (e.g. $\mathbf{b}_2$ in Fig. 2) and $\langle 100 \rangle$, respectively. Dislocations with Burger vectors corresponding to such relatively short lattice translation vectors are perfect ones, which are expected to be observed in compounds with this structure. Such perfect dislocations may be dissociated into partial dislocations, and the character of dislocation dissociation will depend on the relative stabilities and energies of the different faults involved.

The twinning systems of the {111} $\langle 112 \rangle$ type are the variants in which the DO₂₂ superlattice is mechanically twinned without disturbing the DO₂₂ symmetry of the lattice. This is called "ordered twinning" since the ordered arrangement of atoms in the lattice is still retained. On the (111) plane in the DO₂₂ structure, SISF corresponds

Fig. 2 Atomic arrangement on the (111) plane in A_3B compound with DO_{22} lattice structure. The a_1, b_1 and c_1 layers represent the part of the stacking sequence $a_1 b_1 c_1 a_1 b_1 c_1 \dots$ along the $[111]$ direction

to the stacking fault in the underlying f.c.c. structure. The ordered twinning on the (111) $[1\bar{1}2]$ system may result from the propagation of Shockley partials with $\mathbf{b} = \mathbf{b}_s$ on the adjacent (111) planes trailing the SISF.

PLASTIC DEFORMATION OF Al_3Ti AND Al_3Nb

Deformation Mode

The major deformation mode of these compounds is ordered twinning of the $\{111\}\langle 112 \rangle$ system as found earlier for the deformation of Ni_3V by Vanderschaeve and Sarrazin in 1977.^[18] The obtained results have been confirmed by Vanderschaeve and Escaig in 1983.^[19] TEM observation of deformation structures in Al_3Ti have been reported by Yamaguchi et al. in 1988,^[3] Vasudevan et al. in 1989,^[20] and by Morris and Lerf in 1991.^[21] Reip and Sauthoff^[10] showed similar deformation mode for Al_3Nb .

Figure 3a represents deformation twins in Al₃Ti foils of single crystals deformed in compression at 800°C. The (111) twin boundaries are viewed end-on. The corresponding selected area diffraction pattern (SAED) is shown in Fig. 3b, in which the fundamental and DO₂₂ superlattice reflections occur not only from the matrices, but also from the twins.

Figure 4 shows a high-resolution electron microscopy (HREM) image. The twin boundary, which is located horizontally at the center of the image, is seen to be atomistically flat and parallel to (111). The atomic arrangement

characteristic of Al_3Ti projected onto $(1\bar{1}0)$ is evident in both the matrix and the twin. Image calculations indicate that the bright spots correspond to the atomic rows composed of alternately arranged Al and Ti atoms while weakly bright spots correspond to Al atoms. Twinning does not disturb the DO_{22} order. This is consistent with the SAED pattern in Fig. 3b.

At high temperature, the four $\langle 112 \rangle$ -type ordered twinning systems are augmented by slip of the types $\langle 110 \rangle$, $\langle 100 \rangle$ and $\langle 112 \rangle$, respectively. In particular, significant deformation occurs by slip on $(001)\langle 110 \rangle$ at temperatures higher than 600°C . Dislocations with $\mathbf{b} = \langle 110 \rangle$ on (001) are widely dissociated into two superlattice partial dislocations with $\mathbf{b} = \langle 110 \rangle$ separated by a ribbon of APB-I on (002) as illustrated in Fig. 5, a bright-field image of superlattice dislocation with $\mathbf{b} = [110]$ in an Al_3Ti single crystal deformed at 800°C . The figure is viewed nearly along $[001]$ with $\mathbf{g} = 0\bar{2}0$. The corresponding dark-field image with (201) superlattice reflection shows the ribbons of APB-I with the displacement vector $\frac{1}{2}[110]$.

These types of dislocations are splitting on $\{111\}$ planes; The spacings between the partials on (001) and $\{111\}$ have been measured, giving the values of APB-I energies of 25–32 mJm⁻² on (001) and 190–200 mJm⁻² on $\{111\}$.^[22] The energy of the $\frac{1}{2}\langle 110 \rangle$ -type APB in the Li₂ structure is also lowest on $\{001\}$, and the motion of pairs of superlattice partial dislocations with $\mathbf{b} = \frac{1}{2}\langle 110 \rangle$ joined by the APB on (001) is the major high-temperature deformation mode in many Li₂ compounds. Slip of the type (001) $\langle 110 \rangle$ may be

Fig. 3 (a) TEM bright-field image of deformation twins in a single crystal of Al_3Ti deformed in compression at 800°C . (b), (c) Corresponding SAEDX-pattern; indexed closed and open circles represent fundamental and superlattice reflections^[3,21]

Fig. 4 HREM image of deformation twin in the single crystal of Al_3Ti

Fig. 5 Bright-field image of dislocation structures in a Al_3Ti single crystal deformed in compression at 800°C

a common high-temperature deformation mode in LL_2 and LL_2 -derivative, long-period ordered structures.

Perfect dislocations with $\mathbf{b} = \frac{1}{2}\langle 112 \rangle$ (e.g. $\mathbf{b}_2$ in Fig. 2) were not detected in the earlier studies.^[2] Dislocations of the $\frac{1}{2}\langle 112 \rangle$ -type have recently been found to exist in Al_3Ti . These are dissociated as $\frac{1}{2}\langle 112 \rangle \rightarrow \frac{1}{6}\langle 112 \rangle + \frac{1}{3}\langle 112 \rangle$, and the separation has been measured.^[21] From this the SISF energy of 91–1097 mJm⁻² have been determined. This value is not so low as it would be expected from the abundance of ordered twins in deformed specimens of Al_3Ti . The observation of extensive twinning in this compound is believed to be a reflection of the difficulty of dislocation propagation rather than a reflection of easy twinning. The only glissile screw dislocation with a planar core has been found to be the Shockly partial $\frac{1}{6}\langle 112 \rangle$ bounding an SISF. Other screw dislocations, such as the partial dislocation $\frac{1}{3}\langle 112 \rangle$, and the superlattice partial dislocation $\frac{1}{2}\langle 112 \rangle$, bounding an APB-I on (001), are all sessile, and hence thermal activation is needed for their movement.

Bands of $\frac{1}{2}\langle 112 \rangle$ dislocations trailing the APB-I on (001) and loosely coupled in pairs have been often found where twins intersect. The (001) $\langle 110 \rangle$ slip corresponds therefore to the conjugate deformation mode to the complementary ordered twinning system.^[23]

Temperature Dependence of Strength – Single and Polycrystals

Typical stress-strain curves of Al_3Ti single crystals at 800°C in two different compression axis orientations are shown in Fig. 6. In region I of the [100]–[010]– $[\bar{1}10]$ stereographic triangle all four ordered twinning systems can be activated since twins on the four ordered twinning systems produce compression strain, and hence deformation by ordered twinning can occur rather easily when

Fig. 6 Stress-strain-curves of Al_3Ti single crystals with different orientations

compared with other orientations. As seen from the stress-strain curve for orientation (A) serrations occur for orientations in this region. This feature is due to the discontinuous generations of twins.

In region II, two of the four ordered twinning systems can be operative and none of them in region III. For orientations in region II with large values of the Schmid factor for slip on (001) $[1\bar{1}0]$, a smooth stress strain curve exhibits which is like that for orientation (B). The twinning stress is plotted as a function of temperature in Fig. 7. Although the scatter in the results is large, the resolved twinning stress is almost independent of temperature. In contrast, the yield stress exhibited by specimens which are deformed by slip in the (001) $\langle 110 \rangle$ glide system shows a strong temperature dependence. The critical resolved shear stress (c.r.s.s.) for slip, calculated by resolving the yield stress on the corresponding slip system, is shown as a function of temperature in Fig. 7 (dashed line). This strong temperature dependence of the c.r.s.s. for slip of the (001) $\langle 110 \rangle$ type in the DO_{22} structure has been interpreted in terms of the low mobility of superlattice partial dislocations of the type $\mathbf{b} = \frac{1}{2}\langle 110 \rangle$ due to their sessile core structure by Khantha, Vitek, and Pope.^[24]

Polycrystalline Al_3Ti material prepared by conventional vacuum metallurgy technology contains small volume fractions of finely dispersed secondary phases, mainly aluminium. This is due to the peritectic reaction and the formation of the in congruently solidifying intermetallic compound.

The dispersion of aluminium surrounding the compound grains will enhance the plastic deformation of Al_3Ti . The two-phase Al_3Ti/Al mixture containing more than 85 vol% Al_3Ti can be extruded at 600°C with a ratio of reduction in area of 10:1. The overall deformation must be much greater than the deformation of the hard Al_3Ti component of the composite, which suffers significant plastic deformation.

Fig. 7 Resolved shear stress for slip and twinning in Al_3Ti single crystals in dependence on temperature

In particular, fine-grained, two-phase composites exhibit good compressive ductility even at room temperature. The following interpretation has been proposed: the presence of aluminium surrounding the Al_3Ti grains provides a sink for the relief of stress concentrations during the deformation of Al_3Ti , leading to a pseudo-augmentation of the low-temperature deformation of Al_3Ti .^[25]

In contrast to Al_3Ti and Al_3V Al_3Nb melts congruently. This makes the production of Al_3Nb in larger quantities easier. The remarkable high elastic stiffness of Al_3Nb at elevated temperature, e.g. Young's modulus of 225 GPa at 600°C and its high proof strength and creep resistance at temperatures beyond 1000°C are of considerable importance for high temperature applications. Reip and Sauthoff studied the short-term behaviour^[10] and the creep properties of pure Al_3Nb and of some alloy modifications, such as $\text{Al}_3(\text{Nb}_{0.75}\text{Ti}_{0.25})$ and some others.^[10,13]

The temperature dependent yield stress of polycrystalline Al_3Nb and $\text{Al}_3(\text{Nb}_{0.75}\text{Ti}_{0.25})$ compounds and for comparison the Al_3Ti compound are shown in Fig. 8. At medium temperatures between 600°C and 775°C Al_3Nb exhibits pest phenomena because of preferential grain

Fig. 8 Yield stress vs. temperature curves for Al_3Ti , Al_3Nb and $\text{Al}_3(\text{Nb}_{0.75}\text{Ti}_{0.75})$ ^[10]

Fig. 9 Twinning formation in Al_3Nb polycrystals^[10]

boundary oxidation.^[26,27] However, this problem can be overcome by alloying titanium to the Al_3Nb compound. From Fig. 8 it can be seen that the proof stresses of the Al_3Nb and $\text{Al}_3(\text{Nb}_{0.75}\text{Ti}_{0.25})$ alloys are considerably higher than those of Al_3Ti .

The active slip systems are identical for all these compounds, and the major deformation mode is twinning revealing in individual Al_3Nb grains, shown in Fig. 9. The fracture toughness of Al_3Nb based compounds are rather poor. The critical stress intensity factor K_{IC} at room temperature is about 2.5 to 3 $\text{MPa} \sqrt{\text{m}}$ and increases with increasing test temperature up to 5 $\text{MPa} \sqrt{\text{m}}$ at 800°C. However, above 400°C macroscopic plasticity, indicated by a plastic zone at the crack tip, gives evidence for thermally activated dislocation emission and dislocations glide, which is also strongly related to the applied strain rate.

The creep strength of the stoichiometric unalloyed Al_3Nb material is relatively low, e.g. a stress of 10 MPa leads to an amount of 1% creep strain in 500 h, and creep rupture occurs in 2300 h. This unique behaviour is in contrast to the high yield stresses achieved, which compare favourably with those of super alloys.

This fact illustrates the different high temperature strengthening behaviour of inter metallic with complex DO_{22} structure and multi component superalloys with large volume fractions of L_{12} or B_2 compounds with higher symmetry finely dispersed throughout an f.c.c. or b.c.c. nickel, cobalt or iron matrix.

Creep in Al_3Nb is due to dislocation climb, accompanied by subgrain formation. The secondary creep rate is described by the Dorn equation for dislocation creep:

$$\dot{\epsilon} = A \frac{D_{\text{eff}} G |b|}{k \cdot T} \left(\frac{\sigma}{G} \right)^n \quad (3)$$

where $\dot{\epsilon}$ is the strain-rate, A is a structure term, $D_{\text{eff}} = D_0 \exp(-Q/RT)$ is the effective diffusion coefficient, G represents the temperature dependent shear modulus, b is the Burgers vector, T is the test temperature, k is the Boltzmann constant, σ is the applied stress, and n is the stress exponent. Fig. 10 illustrates secondary creep curves of a variety of $\text{Al}_3(\text{Nb}, \text{Ti})$ and $\text{Al}_3(\text{Nb}, \text{Ni})$ alloys.^[25] The stress exponent n is between 3 and 5 and indicates clearly power law creep. The n value was determined to be 3.6 and the overall activation energy was 360 kJ/mol. The temperature dependent activation energy of the shear modulus is about 35 kJ/mol and almost the remaining 325 kJ/mol refers to thermally activated diffusion processes involving dislocation climb for subgrain formation and reinstating the ordering.

The isostructural compound Al_3V is regarded as promising for applications in nuclear reactor technology. The melting temperature is only slightly higher than that of Al_3Ti and a similar deformation behaviour is expected. However, the yield stress is higher than that of Al_3Ti by a factor of about 2 and there is no ductility in compression below about 400°C.

Fig. 10 Secondary creep rate vs. reciprocal temperature of Al_3Nb and divers $\text{Al}_3(\text{Nb}, \text{Ti}, \text{Ni})$ alloys^[25]

Microalloying with titanium improves the ductility in compression—at the expense of the yield stress—to such an extent that $\text{Al}_3(\text{V}_{0.95}\text{Ti}_{0.05})$ shows a compressive strain of about 7%. Increasing the Ti content leads to a deterioration in the properties, i.e. $\text{Al}_3(\text{V}_{0.75}\text{Ti}_{0.25})$ is significantly stronger than Al_3V , but can only be deformed plastically at 700°C and above.

It is noted that according to first-principles calculations, the Al_3Ru compound also has the DO_{22} structure and is closely related to Al_3V . The deformation behaviour of Al_3Ru is expected to be similar to that of Al_3V but with enhanced ductility. The main strategy for improving the ductility of Al_3X types of aluminides is to decrease the APB energy on the (001)-plane. Introducing a $\frac{1}{2}\langle 110 \rangle$ APB on (001) in the DO_{22} structure is equivalent to creating a local stacking of (001) layers of the DO_{23} or L1_2 type. This would also reduce the magnitude of the Burgers vector of the dislocations carrying slip on $(001)\langle 110 \rangle$. Another important aspect is the refinement of slip and/or twins. The presence of massive macro twins often leads to brittle fracture.^[29] As already pointed out, alloying of Al_3V by Ti leads to an enhancement of twinning and a refinement of twins and consequently the compressive fracture strain of the $\text{Al}_3(\text{V}, \text{Ti})$ aluminides will be improved.

(Al, X)₃Ti ALUMINIDES WITH L₁₂ STRUCTURE

The ordered f.c.c. L1_2 structure of Al_3Ti will be stabilized if an appropriate number of d-electrons is removed from the Ti sites. This can be accomplished by decreasing the charge transfer from Al to Ti by replacing Al atoms with other less electro-positive elements which act as electron acceptors. The DO_{22} type of structure will be changed to the L1_2 structure by alloying Al_3Ti with transition metals

X, such as Cr, Mn, Fe, Co, Ni, Cu, Rh, Ir, Pd, Pt, Ag and Au, respectively.

X in $(\text{Al}, \text{X})_3\text{Ti}$ stands for one or more substitutional elements in ternary, quaternary and even in quinary compounds. After Kumar et al. the Cr-, Mn- und Fe-modified L1_2 trialuminides exhibit continuous solubility in each other.^[30–32] However, the maximum concentration of substitutional elements in the L1_2 phase is in the range of 4 to 12 at%, regardless of the number of substitutional elements. Several parameters, such as electron-to-atom ratio, lattice constant of the L1_2 phase, Pettifor's Mendeleev number^[33] and atomic radius, have been plotted versus the amount of element X in the L1_2 phase.^[34] The best correlation has been found to be between the amount of element X in the L1_2 phase and the shortest distance between atoms of the element X in its pure structure. This seems to suggest that the simple charge transfer model may not be enough to describe quantitatively the observed L1_2 stabilization effects of ternary alloying additions. Recently, Hong and Freeman^[35] have made first-principles calculations on the effects of substituting Cu for either Ti or Al in Al_3Ti and reported that Cu as a ternary addition strongly favors the Al site and the substitution of Cu for Al causes a similar change in bonding character in the new material as tetragonal distortion did in pure Al_3Ti .^[36] Similar results have been achieved also by Eberhart et al.^[37] Such efforts to specify the role of ternary alloying elements in structural stability are needed for a more complete understanding of the stabilization of the L1_2 structure in the trialuminides.

Also for the DO_{23} compound Al_3Zr a partial substitution of ternary elements, such as Cr, Fe, Ni and Cu for Al has been found to result in ternary $(\text{Al}, \text{X})_3\text{Zr}$ -based L1_2 phases.^[38] The elements V, Co^[34] and Mn^[39,40] have been added to the list of alloying elements known to form ternary $(\text{Al}, \text{X})_3\text{Zr}$ -compounds.

For the DO_{22} compound of Al_3Nb no ternary L1_2 phases have been found in the vicinity of the trialuminide composition.^[41] This is because the differences in the electronic total energy for the Group IV transition metal trialuminides between the stable DO_{22} or DO_{23} and the hypothetical L1_2 phases are much smaller than those for Group V transition metal trialuminides.^[42] Single-phase L1_2 -structured Al_3Ti , Al_3Zr and Al_3Hf might be achieved through mechanical alloying of a mixture of pure elemental powders at the corresponding composition, although they transform to the stable structure in the temperature range from 500 to 700°C.^[43]

Processing and Microstructure

Table 3 lists a representative number of $\text{Al}_3(\text{Ti}, \text{X})$ alloys – L1_2 variations – investigated together with the preparation methods and measured properties. The powder processing, rapid solidification, arc melting, induction melting, levitation melting, hot isostatic pressing (HIP), hot forging and hot extrusion will cause different

mechanical properties, even though the compounds have the same composition. This indicates that the microstructure and mechanical properties of differently processed and investigated $\text{Al}_3(\text{Ti}, \text{X})$ alloys with L_{12} structure may not be directly comparable, as evidenced by the fact that their mechanical properties often vary within a certain scatter band. Results of various studies^[43] showed that the L_{12} phase field contracts with decreasing temperature, leading to precipitation of a second and sometimes a third phase at low temperatures. It is difficult to obtain single-phase L_{12} trialuminide compounds prepared by conventional ingot metallurgy. These normally contain precipitates of second and third phases. Even when compounds appear to be single phase on the scale of optical microscopy, finely dispersed secondary phase precipitates are often observed in TEM (Wu et al.,^[44] DiPietro et al.,^[45] Nick et al.^[46]). The distribution of such precipitates tends to vary depending on heat-treatment parameters, such as temperature and cooling rate. The mechanical properties, specifically yield stress, strength, ductility and fracture toughness may vary with the distribution of precipitates and other defects, such as pores and micro blow holes. Precipitates may be eliminated by a homogenization heat treatment at temperatures generally above 1000°C . The same homogenization treatment, however, has been known to increase the volume fraction of pores through the Kirkendall mechanism.

Recently, hot forging, (Kumar and Brown,^[31] Chen et al.,^[47]) and hot extrusion (Schneibel et al.^[48]) have been shown to be effective in minimizing the volume fraction of pores and secondary phase precipitates, and hence increasing the ductility of L_{12} trialuminide compounds. Another important fact is that hot-worked compounds generally show fine-grained microstructures with almost no pores. If the chemical composition is chosen properly, they contain only a small amount of secondary phase precipitates compared to as-cast ingots. No appreciable plastic strain has been observed in bending or tension test of L_{12} trialuminides produced without hot working. However, Schneibel et al.^[48] have observed that small but definite plastic strain of 0.16% in bending of a hot-extruded Cr-modified compound at room temperature occurred. This clearly indicates the importance of microstructural control to achieve optimum mechanical properties in the L_{12} trialuminide compounds. Hardness measurements have been extensively used to evaluate the brittleness by measuring the total crack length formed around a Vickers indent or the maximum crack-free load.^[46,49] However, in evaluating the strength and brittleness by hardness measurements, it has to be considered that the hardness of L_{12} trialuminides is load dependent. It decreases with load until a plateau value is reached. The maximum crack-free load is usually very close to the load value at which the hardness becomes load dependent. Hardness measurements showed that the strength and brittleness of ternary L_{12} trialuminides vary

greatly with ternary alloying elements, but their hardness is always lower than that of binary Al_3Ti regardless of ternary alloying elements.^[50]

Interestingly, it was found that there is a systematic increase in hardness and a decrease in crack resistance with increasing atomic number of the ternary alloying element of the fourth period from Cr to Cu. There is a systematic decrease in lattice parameter and an increase in modulus with increasing atomic number of the ternary element. Mikkola et al.^[51] suggested that the higher the atomic number of the ternary element, the stronger is the d-d bonding in the L_{12} trialuminide, leading to increased hardness and brittleness. A small plastic strain in bending has been observed only for Cr- and Mn-modified compounds. Winnicka and Varin,^[52] on the other hand, have shown that in trialuminides stabilized with Cr, Mn, Fe and Cu, the hardness is rather independent of the atomic number of the ternary element. The hardness increases almost linearly with increasing Ti content. A similar dependence of strength on Ti content has also been observed in compression for Mn- and Fe-modified compounds.

Nic et al.^[46] investigated the variation in hardness with Ti and Cr content in Al-Cr-Ti compounds in which the phases present were identified by powder X-ray diffraction and TEM. As shown in Fig. 11, compounds with compositions within the L_{12} single-phase field have lower hardness values than compounds composed of two and three phases. In the composition range from 8 to 13 at% Cr and 23 to 25 at% Ti, where the lowest hardness

Fig. 11 Variation in hardness of Al-Ti-Cr compounds^[46]

occurred, the hardness only slightly increases with Cr and Ti concentrations. However, in compounds with a Ti content higher than 25 at%, the hardness depends strongly on Cr and Ti content. In compositions containing more than 25 at% Ti, a large amount of finely dispersed precipitates have been observed in TEM. It is important to understand the mechanical properties of trialuminides in a microstructure/property relationship on the nanometer scale. X-ray and other measurements of the type and concentration of structural defects in trialuminides are needed to clarify the effects of off-stoichiometry on the mechanical properties.

Temperature Dependent Strength Properties

Several investigations on the temperature dependence of the compressive yield stress of various $(\text{Al}, \text{X})_3\text{Ti}$ compounds have been performed since they are brittle under the action of tensile stress at low temperatures. Figure 12 shows some representative yield stress-temperature curves published for various ternary L_{12} trialuminides. The compositions are given in at%. The stress level and the shapes of the curves vary greatly with composition, even for the same nominal composition. This may be largely due to the difference in preparation method and hence the difference in microstructure of the compounds investigated. However, some general features of the yield stress-temperature profile occurred.

The yield stress increases rather rapidly with decreasing temperature below room temperature. Since at low temperatures the yield stresses of Al_3Ti -based L_{12} compounds depend more strongly on temperature than those of L_{12} compounds, such as Ni_3Al – in which $\langle 110 \rangle$ dislocations dissociate into two $\frac{1}{2}\langle 110 \rangle$ superlattice partial dislocations separated by an APB; a different dissociation scheme is believed to occur in the Al_3Ti -based trialuminides, if $\langle 110 \rangle$ dislocations dissociate into two $\frac{1}{2}\langle 112 \rangle$ superpartials separated by an SISF. The observed temperature dependence is well explained in terms of the nonplanar

core structure of the superpartials (Yamaguchi et al.,^[53] Paidar et al.,^[54] Tichy et al.^[55]). However, some investigators have reported either no dissociation or a dissociation of the APB type. Two exceptions are the results of Hu et al.^[56] and Inui et al.^[57] The existence of a large number of antisite defects may contribute to strengthening at low temperatures.

Generally, the yield stress curves possess a plateau or a slight increase with temperature at intermediate temperatures. For iron and chromium modified compounds, most investigators have observed only a plateau or slightly anomalous behavior. The magnitude of the anomalous strengthening observed in L_{12} trialuminides is considerably smaller than that observed in L_{12} compounds such as Ni_3Al . Unlike Ni_3Al , the c.r.s.s. for $\{111\}\langle 110 \rangle$ slip in L_{12} trialuminides such as the Fe-modified ones is almost independent of orientation in the plateau or of the anomalous strengthening temperature range.^[44,58] Thus, even if anomalous strengthening occurs in L_{12} trialuminides, the mechanism behind the anomaly in the L_{12} trialuminides may be different from the mechanism responsible for Ni_3Al . In the plateau or anomalous strengthening temperature range serrations have often been observed in stress-strain curves for most trialuminides, indicating that dynamic strain aging contributes to deformation.^[59–61]

The specific strength of high-strength aluminium alloys, such as 7075-T6 is higher than those of the trialuminides at temperatures lower than 150°C. However, the yield stresses of the L_{12} trialuminides are showing plateaus or a slight increase up to 600–800°C depending on composition, and thereby they are superior to high-strength titanium alloys in their specific strength at temperatures higher than 600°C. Even at room temperature, the strength can be markedly increased by utilizing precipitation hardening.

The yield stress rapidly decreases with increasing temperature up to 600°C or higher. The extent and the onset temperature of the rapid decrease of yield stress depend on the compound and the composition. For example, $\text{Al}_{63.7}\text{Fe}_{8.2}\text{Ti}_{28.6}$ exhibits a marked decrease in yield stress above 600°C, but to a much lesser extent than $\text{Al}_{63.7}\text{Fe}_{7.6}\text{Ti}_{28.7}$.

The yield stress markedly increases with increasing Ti content in compounds with higher Ti contents. The strong compositional dependence of the yield stress was first noticed by Zhang et al.^[49] in a series of Mn-modified compounds ($\text{Al}_{61}\text{Mn}_{10}\text{Ti}_{29}$, $\text{Al}_{67}\text{Mn}_8\text{Ti}_{25}$ and $\text{Al}_{68}\text{Mn}_9\text{Ti}_{23}$). The compound with the highest Ti content exhibits a yield stress that is almost twice as high as the others. The large increase in yield stress with Ti content in the Fe-modified compounds has been attributed to the existence of finely dispersed secondary phase precipitates, which were imaged in TEM. However, the effects of solid solution hardening due to structural defects, such as antisite atoms and vacancies, on the mechanical properties are not yet well known.

Fig. 12 Yield stress vs. temperature curves of a variety of L_{12} -Al-Ti-X alloys

Plasticity and Fracture

$L1_2$ trialuminides apparently exhibit at room temperature ductility in compression, usually with a macroscopic fracture strain of more than 10%. However, this apparent ductility is accompanied by microcracking. Extensive internal and external microcracking are usually observed even at a plastic strain as low as 1%. In contrast, all $L1_2$ trialuminides appear to be very brittle under the action of a tensile stress, although a very small but definite plastic strain has been observed in Cr- and Mn-modified compounds when tested in bending. Consistent with this, the fracture toughness of most $L1_2$ trialuminides is in the range of 2–3 MPa m^{1/2}.^[5,62] Fracture occurs by transgranular cleavage, largely along {110} and {111} planes. The addition of boron at levels of 25 to 1600 ppm has no beneficial effects on the improvement in ductility of $L1_2$ trialuminides. This may be partly because the fracture mode is transgranular cleavage. Wu et al.^[44,48] have reported that single crystals of a Fe-modified compound show no higher ductility than polycrystals of the compound, even in compression. In single crystals tested in compression, fracture occurs by cleavage on a variety of planes including {110}, {111}, {001} and {013}, which is consistent with the result obtained for polycrystals tested in bending.

Uniaxial tensile tests have been carried out by Kumar and Brown^[63] on Mn- and Cr-modified compounds. Plastic strains of 0.2% in the Mn-modified compound but not in the Cr-modified one were recorded at room temperature. These results are contrary to what has been observed in bending tests on Cr-modified compounds by Schneibel et al.^[48] It is reported that the ductility of Cr-modified $L1_2$ trialuminides is extremely sensitive to the surface-finish conditions of the specimens. Figure 13 shows the variation of the tensile yield stress

Fig. 13 Variation in tensile and compression yield stress and tensile ductility as a function of the test temperature^[31]

and elongation of Mn- and Cr-modified compounds with temperature. The compressive yield stress data of the same compounds are also shown in the figure. Interestingly, the tensile yield stress exhibits a rather sharp drop above 350°C, while a relatively smooth decrease is observed in the compressive yield strength over a broad range of temperature. The fracture mode changed from transgranular cleavage at room temperature to a mixed cleavage and intergranular mode at 350°C, and to a completely intergranular mode at temperatures above 650°C. It should be noted that the temperature corresponding to the tensile ductility minimum is not in agreement with the ductility minimum at the temperature for the onset of intergranular fracture.

Fracture Mechanisms

Mechanisms for the poor room temperature ductility of the Al_3X ($X = Ti, Nb, V$) aluminides and the $L1_2$ variations have been discussed on the basis of the Pugh^[64] criterion and the Rice-Thomson^[65] criterion. The Pugh criterion states that a high value of the (K/G) ratio of the bulk modulus K to the shear modulus G is associated with ductility and a low value with brittleness. Modified $L1_2$ trialuminides such as $Al_{67}Ti_{25}Ni_8$ and $Al_{67}Ti_{25}Fe_8$ have in fact lower values of K/G than the ductile $L1_2$ compound Ni_3Al . However, in the review by Mikkola et al.^[51] it was stated that the Cr- and Mn-modified trialuminides, which are somewhat more ductile than the other trialuminides, have the lowest (K/G) values of the Al_3Ti -based trialuminides. This result contradicts the predictions of the Pugh criterion.

The Rice-Thomson criterion is stating that brittle behavior occurs in those materials with values of $G/b\gamma > 7.5$ –10, where b is the magnitude of the Burgers vector and γ is the surface energy of a crack. The $L1_2$ trialuminides have values of G which are comparable to that of the Ni_3Al compound. Although, there is no general agreement on whether $\langle 110 \rangle$ dislocations in trialuminides are dissociated into superlattice partial dislocations at low temperatures or not.

There is little knowledge on the γ -values of the surface energy in Al_3Ti -based trialuminides. However, recently first-principles calculations by Fu,^[14] have shown that the surface energy of Al_3Sc is significantly lower than that for Ni_3Al . Consistent with this, Fu and Yoo^[15] have obtained a low value of the ideal cleavage strength in Al_3Sc . These results suggest that the values of γ in the Al_3Ti -based trialuminides would also be rather low. Considering the fact stated above: the brittleness of the $L1_2$ trialuminides may agree with the Rice-Thomson model. However, the high bonding energy giving rise to high elastic moduli which causes high cleavage strengths in the trialuminides. This might be the most probable reason for the general brittleness of the trialuminides.

OXIDATION BEHAVIOUR OF MONOLITHIC THE Al_3Ti AND Al_3Nb COMPOUNDS AND OF $(\text{Al}, \text{X})_3\text{Ti}$ BASED ALLOYS

Al_3Ti is the only compound in the binary Ti-Al system which forms protective Al_2O_3 scales in air, thereby having much better oxidation resistance than Ti_3Al and TiAl . The rapid growth of TiO_2 in the scales unfavorably affects the oxidation behavior of trititanium and γ -titanium aluminides.^[66,67] Smialek and Humphrey^[68] have investigated the isothermal oxidation kinetics of Al_3Ti over a wide temperature range and related the formation rates to exclusive α - Al_2O_3 scale growth. As already pointed out Al_3Ti ingots prepared by conventional ingot metallurgy methods contain small amounts of aluminium since Al_3Ti does not melt congruently, but exhibits a peritectic reaction involving the aluminium phase near the melting temperature. Oxidation of the second phase, above 660°C , occurs rapidly and results in a high oxidation rate in shorter times and at lower temperatures. However, at temperatures above 1000°C , isothermal oxidation of Al_3Ti exhibits a parabolic oxidation behavior that is controlled by protective α - Al_2O_3 scale formation. The parabolic oxidation rate constant of about $k = 3.510 \cdot 10^{-14} \text{ g}^2/\text{cm}^4\text{s}$ for Al_3Ti have been found to be comparable to α - Al_2O_3 growth kinetics on NiAl . The intrinsic oxidation resistance of single-phase Al_3Ti is excellent. Therefore, attempts have been performed to use Al_3Ti as an oxidation resistant coating material on titanium base alloys α_2 - Ti_3Al and γ - TiAl , respectively.

Coatings based on Al_3Ti have been produced with demonstrated improvements in the oxidation resistance of Ti and Ti-Al substrates using a pack aluminizing process. For protecting super- α_2 Ti-14Al-21Nb alloy in cyclic oxidation, an optimum coating thickness of $40\text{--}70 \mu\text{m}$ (this relates to a mass to area density of $8\text{--}14 \text{ mg cm}^{-2}$) was found by Smialek et al.^[69] They showed that thicker coatings are prone to penetrating cracks which widen, oxidize, and give rise to anomalously large weight gains, despite thin Al_2O_3 scales.

Cubic $(\text{AlX})_3\text{Ti}$ alloys with $\text{X} = \text{Cr}$ and Mn additions do not show only reduced hardness and good compressive ductility but also some tensile ductility at room temperature. Whether these modified cubic compounds have equivalent or better oxidation resistance at high temperatures than binary Al_3Ti is of first concern.

The oxidation resistance of these class of L_{12} variations of Al_3Ti has recently been evaluated by cyclic^[70] and static^[71,72] tests. The investigated materials are ternary compounds of compositions: $\text{Al}_{66-67}\text{M}_{8-9}\text{Ti}_{25}$ ($\text{M} = \text{Ag}, \text{Ni}, \text{Fe}, \text{Mn}, \text{Cr}$). The Ag- and Cr-modified ones show highest and lowest rates of oxidation, respectively.^[71] The formation of TiO_2 has been detected in the Ag-modified compound. The Mn-containing compound shows better oxidation resistance than the Ag-containing one at lower temperatures, but the difference between the two compounds becomes smaller as the temperature is increased to

Fig. 14 Specificweight of different Al_3Ti based compounds during cyclic oxidation at 1200°C (Parfitt et al. [1991])

1200°C . The results of the oxidation resistance of the Cr- and Mn-modified compounds by cyclic oxidation testing at 1200°C in air are shown in Fig. 14. The Mn-modified compounds perform very poorly in this test, while the Cr-modified ones perform extremely well, and in fact display as good or better oxidation resistance than NiAl -based compounds which are considered to have excellent oxidation resistance. This is because the Cr-modified compound forms a protective scale of Al_2O_3 while the Mn-containing compounds form mixed $\text{Al}_2\text{O}_3 + \text{TiO}_2$ scales. The $\text{Al}_{67}\text{Cr}_8\text{Ti}_{25}$ compound with oxygen-active elements would likely reduce spallation to very low levels during the severe cyclic test. Such effects are similar to the behaviour of NiAl , whose resistance to spalling is improved dramatically by the addition of small amounts of oxygen-active elements such as Zr and Y.^[73]

It is of interest that isothermal oxidation of binary Al_3Ti results exclusively in Al_2O_3 scale, while cyclic oxidation is degraded by the formation of TiO_2 along with Al_2O_3 . The formation of TiO_2 during cyclic oxidation of binary Al_3Ti has been interpreted as follows: The spallation accelerates the rate of aluminium removal and may convert the surface of the Al_3Ti compound to a two-phase mixture of $\text{Al}_3\text{Ti} + \text{TiAl}$; then, nonprotective mixed $\text{TiO}_2 + \text{Al}_2\text{O}_3$ scales are formed on a TiAl layer and further oxidation proceeds at a higher rate. Such compositional resistance of a line compound may be avoided in ternary L_{12} compounds based on Al_3Ti , since they generally have a compositional range, e. g. an Al range of $62\text{--}67.5 \text{ at}\%$ for $(\text{Al}, \text{Cr})_3\text{Ti}$ compounds. The Fe- and Ni-modified compounds have been reported to exhibit excellent static oxidation resistance in air at temperatures up to 1100°C , although their oxidation resistance has not yet been evaluated in severe cyclic oxidation testing.

Recently, Schneibel et al.^[48] have examined compression creep properties, Young's modulus and thermal expansion of $\text{Al}_{67}\text{Cr}_8\text{Ti}_{25}$. The coefficient of thermal expansion of the Cr-modified L_{12} compound is about half that of aluminium and 30% higher than that of titanium alloys.

The use of the Al_3Ti compound as protective coating on titanium alloys gives rise to tension strain in the coating layer during cooling to room temperature because of its larger thermal expansion coefficient than those of the Ti alloy substrates. However, cracking due to tension strain in the cubic Cr-modified compound is expected to be less severe than in binary Al_3Ti . This is due to its isotropic structure and the finite tensile ductility. In surveying the mechanical properties and oxidation resistance of the L_{12} variations of Al_3Ti , some of this class of materials, in particular the Cr-modified L_{12} compounds, exhibit improved oxidation resistance.

Pure Al_3Nb does not form a protective Al_2O_3 scale exclusively. However, by alloying to favor the selective oxidation of Al, a continuous Al_2O_3 scale can be grown on Al_3Nb . As a ternary addition to Al_3Nb , Cr is reported to be more effective than Ti and Si in growing a continuous Al_2O_3 scale. Oxygen-active elements have a beneficial effect on the oxidation behavior of Al_3Nb . An Al_3Nb -based compound with a composition of Al-24Nb-7Cr-0.5Y-1.6Si (at%) has been reported to exhibit excellent cyclic oxidation resistance for 100 h at 1200°C, being nearly equivalent to NiAl + Zr.^[27,74] The oxidation behavior and kinetics of Al_3Zr and its L_{12} modifications have not yet been investigated in greater detail.

POTENTIAL APPLICATIONS OF TRIALUMINIDE ALLOYS

In this chapter, a wide cross section of properties of trialuminides and its L_{12} variations have been reviewed. Early studies on Al_3Ti , Al_3V , Al_3Nb and Al_3Zr in the DO_{22} structure form stimulated much additional work on their L_{12} variations; however, interest in pure Al_3Ti quickly decayed since it is quite brittle at room temperature, and no significant improvement in ductility has been achieved in spite of various attempts to enhance slip and twinning by microalloying. In contrast, considerable interest on the L_{12} based Al_3Ti materials has been arisen because of its good compressional ductility and of some tensile ductility, especially in the Cr- and Mn-modified L_{12} compounds. In spite of alloying with transition metals such as Cr, Mn, Fe and Ni, the L_{12} variations of Al_3Ti still possess a desirable density of about 4 Mg m⁻³. Their melting points are as high as ca. 1350°C and their creep properties are at least comparable with those of TiAl.^[48] Oxidation resistance was a concern. However, the Cr-modified compound $\text{Al}_{67}\text{Cr}_8\text{Ti}_{25}$ has recently been found to exhibit excellent cyclic oxidation resistance at 1200°C. Its oxidation resistance is as good or better than that of NiAl alloys. From surveying the physical metallurgy and mechanical properties of the L_{12} variations of Al_3Ti , it is concluded that some of this class of materials in particular the Cr-modified compounds of superior oxidation resistance is considered as high-temperature coating and composite-matrix materials.

It should be noted that DiPietro, Kumar and Whittenberger et al.^[45] have reported results on compressive studies of TiB_2 particulate composites with Al_3Ti -based L_{12} compounds as matrices in dependent on matrix composition, amount of TiB_2 , processing technique, temperature and strain rate. Below 600°C, their strength-to-density ratio has been reported to be approximately four times those for superalloys. However, advantage is not maintained above 730 or 830°C. Creep responses (flow strength/density versus strain rate) of a monolithic Fe-modified L_{12} compound containing Nb have been found to be better than a nickel based superalloy. These results clearly imply that the Al_3Ti -based L_{12} trialuminides are worthy of more extensive studies as composite matrices showing good oxidation resistance.

Introduction to Aluminum

Alexey Sverdlin

Bradley University, Peoria, IL, United States

Abstract

Aluminum is the most heavily consumed non-ferrous metal in the world with an annual consumption of approximately 24 million tons of which it is estimate that 75% of this total amount is primary aluminum (aluminum extracted from ore). This article provides an overview of aluminum ores and their composition, reduction of aluminum, production of commercial quality aluminum, extraction, refinement and the production of ultrapure aluminum.

Keywords: Alcoa chloride process; Aluminum ore; Bayer process; Reduction; Refinement; Toth process.

INTRODUCTION AND GENERAL OVERVIEW

Aluminum is the most heavily consumed non-ferrous metal in the world, with current annual consumption at 24 million tons. About 75% of this total volume, or 18 million tons, is “primary aluminum” (that is, aluminum extracted from ore, as opposed to secondary aluminum which is derived from scrap metal processing).

The ancient Greeks and Romans used alum in medicine as an astringent, and in dyeing processes. In 1761 de Morveau proposed the name “alumine” for the base in alum. In 1807, Davy proposed the name aluminium for the metal, undiscovered at that time, and later agreed to change it to aluminum. Shortly thereafter, the name aluminium was adopted by IUPAC to confirm with the “ium” ending of most elements. Aluminium is the IUPAC spelling and therefore the international standard. Aluminium was also the accepted spelling in the United States until 1925, at which time the American Chemical Society decided to revert back to aluminum, and to this day Americans still refer to aluminium as “aluminum”.

While the opportunities are growing, aluminum must continue to compete with various materials that offer lower cost or other competitive advantages. Aluminum companies must continue to innovate to provide customers with better enabling technologies and superior materials with unique properties. Aluminum manufacturers must explore new process technologies to drive down production costs and make aluminum more competitive. Over the next two decades, investment in research and technology development may likely be the most important factor in product competitiveness.

The process of primary aluminum production can be divided into three independent stages which are, as a rule, carried out at different plants. These are:

- The actual mining of the necessary raw materials (bauxite and a variety of other ores).

- The processing of the ore and preparation of aluminum oxide (alumina).
- Production of primary aluminum from alumina.

World production of primary aluminum totaled 18.056 million metric tons in 1991.^[1] In 1983, more than 70% of the world's bauxite was produced in Australia, Guinea, Jamaica, Brazil, and the former Soviet Union. Bauxite reserves in the United States are less than 1% of the world total (Table 1).

Over the decade, 1983–1993, world production increased 20.3%, and annual growth rate of more than 2.0%. The United States accounted for 22.8% of the world's 1993 production while the European Community accounted for 12.5%. The Republics of the former Soviet Union accounted for 21.0%. The others 43.6% include Asia (11.6%), Canada (10.1%), South America (9.9%), Oceania (8.5%), and Africa (3.4%). The total U.S. supply in 1991 was 8,020 thousand metric tons, with primary production representing about 51.3% of total supply, imports accounting for 17.4%, and secondary recovery representing 31.2%.

World primary aluminum production from 1981 through 1991 is shown in Fig. 1. In 1995, U.S. primary aluminum smelters produced 3.375 million metric tons of aluminum, 17.3% of the total world production of 19.442 million metric tons (Fig. 2). Production of primary aluminum in 1996 in the United States was reported to be 3.577 million metric tons, an increase of about 6% over 1995. Recycling is a critical component of the aluminum industry; in 1995, secondary refiners recovered 3.188 million metric tons of recycled aluminum, representing a little more than one-third of the total U.S. aluminum supply of 9.265 million metric tons.^[2]

The world aluminum industry is composed of six large integrated firms, their subsidiaries, or affiliates Alcan Aluminum Ltd, Aluminum Company of America

Although the United States continues to be the leading producer of primary aluminum metal in the world, its dominance in the industry has begun to wane. In 1960, the United States accounted for slightly more than 40% of the world's production. In 1990, the U.S. share of world production had decreased to 23%. Most of the restructuring of the world aluminum industry began in the late 1970s and continues to this day. Australia and Canada have emerged as major metal producers. Other countries entering the world market today are Brazil, China, Norway, Venezuela, and several countries in the Persian Gulf area.^[2]

Another factor that should be considered in analyzing the domestic aluminum industry is the growing importance of secondary aluminum to the domestic supply situation. Secondary aluminum is defined as aluminum recovered from both new and old purchased scrap. New scrap generated by fabrication of aluminum products may be either home scrap (sometimes called runaround scrap) or prompt industrial scrap. Home scrap is recycled within the company generating the scrap and consequently seldom enters the commercial secondary market. Prompt industrial scrap, however, is new scrap from a fabricator who

does not choose to, or is not equipped to, recycle the scrap. This scrap then enters the secondary market. Old scrap is a product of obsolescence and becomes available to the secondary industry when consumer products have reached the end of their economic life and have been discarded. In 1960, 397,000 metric tons of aluminum was recovered from new and old scrap. In 1990, almost 2.4 million metric tons of aluminum was recovered from purchased scrap. More than half of this secondary aluminum was recovered from postconsumer, or old, scrap.^[1]

By 2000, total U.S. aluminum demand, including primary metal, old scrap, and nonmetal uses, is expected to reach about 9.3 million metric tons, equivalent to an annual rate of growth of 3.2% from the 1983 level. The forecast range of domestic aluminum demand in 2000 is 6.4–13 million tons. Rest-of-the-world aluminum demand in 2000 is expected to range from 29 to 56 million tons.

The annual production of primary metal in the United States is expected to decline to about 4 million tons per year by 2000, and the remainder of the U.S. metal supply is expected to be obtained from other countries and the recycling of old scrap.

THE MAIN TYPES OF ALUMINUM ORES

In nature, aluminum does not exist as a metal because of the high chemical affinity for oxygen. Aluminum compounds, primarily the oxide in forms of various purity and hydration, are widely distributed in nature. In these forms, aluminum is the second most plentiful metallic element on Earth silicon—27.5%. It has been estimated that 8% of the Earth's crust is composed of aluminum. The elements are iron (approximately 5.0%), magnesium (approximately 2.0%), zinc and tin (0.004% each),^[5-7] follow aluminum in content in the Earth's crust.

Although aluminum is one of the most abundant materials in the Earth's crust (invariably as alumina or in some other combined oxide form) any usable ore deposit must be readily amenable to benefice, so that a pure aluminum oxide can be obtained. However, physical benefice of the oxides has not been very successful. Consequently chemical processing has always been necessary to extract pure alumina from the other ingredients associated with it in the deposit. This, therefore, restricts the practical range of materials. Any chemical benefice must be based on selective removal of either the aluminum oxide or the other ingredients. However, frequently the other oxides are chemically similar, and this problem is compounded by the amphoteric behavior of aluminum which makes it extremely difficult to selectively remove the impurities (or "gangue"). Therefore benefice processes are usually based on selective dissolution of aluminum oxide. Kinetically, dissolution in strong caustic is favored. Therefore, mineralogical deposits which contain silica in structural forms that will readily dissolve in concentrated caustics, are unsatisfactory.^[8]

Bauxites contain hydrated forms of aluminum oxide, and are thus the most economically amenable mineralogical sources for chemical benefice to produce alumina. They occur in several different structural forms, depending on the number of molecules of water of hydration and also the crystalline form. The name "Bauxite" is derived from the village Les Baux in the south of France, where the mineral was first commercially exploited.^[8]

Historically, the commercial production of primary aluminum has been based almost entirely on the use of bauxite, in which aluminum occurs largely a hydrates of alumina. However, deposits containing aluminum in the other mineral forms are widespread and virtually inexhaustible. The average aluminum content of the Earth's crust has been estimated at 15.7% on an Al_2O_3 basis, and deposits containing more than 13% aluminum (25.0% Al_2O_3) are common.^[3]

Information on bauxite reserves and resources ranges from reports based on thorough exploration for some deposits to reports giving only a total quantity estimate based on unspecified field work for other deposits. The reserve and reserve-based estimates in Table 3 are the result of evaluating data and information obtained from

Table 3 World bauxite resources, January 1985^[3] (million metric tons of bauxite)

many sources. Salient bauxite statistics from 1945 through 2000 presented in Fig. 5.

Major deposits of bauxite are located in countries remote from the main aluminum producing and consuming

Fig. 5 Salient bauxite statistics

centers in North America and Europe. Most of the high grade bauxite deposits suitable for extraction of alumina occur in tropical or semitropical regions. In all these deposits, the hydrated aluminum oxide is invariably associated with small amounts of compound of iron, silicon and titanium and trace amounts of other elements. Most of the tropical deposits are of a blanket-type which can be over 7m thick and mined by open-cast methods. Inter-layered deposits and small pocket deposits are also found. Some of them are also amenable to open-cut mining. In physical appearance, the various bauxite deposits can differ considerably. This is due to prior weathering, basic variations in the crystalline form of the hydrated aluminum oxide, and variations in the nature of impurities associated with it.^[8]

Bauxite is found within 30 million-year-old weathered rock, which has broken down to leave a high proportion of aluminum bearing minerals. A combination of rainfall and organic acids caused the weathering of the dolomite and granite rocks until most of the elements are dissolved, leaving a reddish soil known as laterite which is rich in aluminum oxides and iron. The developed bauxite deposits are common throughout the world. Pure alumina (Al_2O_3) can be reduced comparatively cheaper and easier from bauxite. From alumina, the metallic aluminum can be received by electrolysis.^[8-12] However, the comparative

limitation of bauxite deposits and complex mining operations at many bauxite deposits have resulted the necessity of development of other types of raw materials to extract aluminum profitably.

The major deposits in central Arkansas were formed by weathering, during Eocene time, or nepheline syenite intrusive of Late Cretaceous age. The predominant aluminum oxide mineral in the bauxite is the trihydrate form, gibbsite. Some deposits are residual on the igneous rock and clay, while others are the result of transportation and accumulation of eroded deposits. The composition of the ore mined in Arkansas varies widely within a range of 40% to 52% Al_2O_3 , 7% to 17% SiO_2 , and 6% to 12% Fe_2O_3 .

The bauxite deposits in the coastal plain of Alabama and Georgia are found as lenses within flat-laying beds of kaoinitic clay, which are overlain by sand and clays of early Tertiary age. The grade of the bauxite is 48% to 56% Al_2O_3 , 12% to 16% SiO_2 , and less than 2.5% Fe_2O_3 . The low iron oxide content qualifies this ore for use in refractories and chemicals.^[3]

In Jamaica, the bauxite deposits fill sinkholes, channels, and blanket uneven depressions in the karst surface of limestone of middle Tertiary age. Jamaican bauxite is largely gibbsitic, although mixture containing up to 20% monohydrate alumina occur. Ore grade is 45% to 49%

Al_2O_3 , 0.8% to 8% SiO_2 , 17% to 22% Fe_2O_3 , and 2.5% TiO_2 . The bauxite deposits in the Dominican Republic and Haiti are similar in grade, age and genesis, and are identified as “Jamaican type” bauxites.

Bauxite deposits in Suriname and Guyana are scattered throughout a narrow belt extending along the contact between the Precambrian crystalline rocks of the Guyana Shield and the sedimentary beds of Tertiary or later age that form the coastal plain. The alumina mineral is gibbsite and the ore is high grade: typically 55% to 60% Al_2O_3 , 2% to 5% SiO_2 , and less than 3% Fe_2O_3 .

In the large deposits discovered in northern Brazil since 1967, the bauxite occurs as a residual capping on dissected plateaus several hundred feet above the Amazon or other nearby rivers. The ore has developed on unconsolidated Tertiary sediments and is converted by 12–30% of kaolinitic clay. The approximate grade after washing is 55% Al_2O_3 , 3.5% SiO_2 , and 11% Fe_2O_3 .

The Weipa bauxite deposit in Queensland, Australia, occurs in the upper portion of a flat-lying laterite that extends for more than a hundred miles along the West Coast of the Cape York Peninsula. The bauxite ranges in thickness from a few feet to 30 ft and is covered by a soil overburden 1–3 ft thick. The deposits are associated with Tertiary kaolinitic sands, from which they were probably derived. The grade of the beneficiated bauxite is 53% to 58% Al_2O_3 , 4% to 7% SiO_2 , and 12% Fe_2O_3 .

In Guinea, the large Sangaredi bauxite deposits occur as laterite caps on inland plateaus at elevations of 900 ft or more above sea level. Most of the bauxite is believed to have formed through weathering of schists and sandstones of Devonian or Post-Devonian Age. Typical ore contains 57% to 60% Al_2O_3 , less than 1% SiO_2 , and 2% to 4% Fe_2O_3 .

Many of the European bauxite deposits are associated with pockets and depressions in the karst weathering surface of Mesozoic limestone beds that have been buried, folded, and faulted subsequent to the development of the bauxite. European bauxites are composed predominantly of monohydrate alumina minerals, although some gibbsitic deposits are mined in Hungary and a few other countries.^[3]

Bauxites represent mountain rocks, the main component of which is aluminum oxide. Bauxite contains a large number of impurities such as silica, iron and titanium oxides, and various other elements mostly in minor or trace amounts.^[13] The amount of free aluminum oxide can vary. Typical economic bauxite ores contain greater than 45% alumina, less than 12% iron oxides and less than 8% of combined silica. The bulk density of most bauxites is between 1.3 and 1.9 g/cm³. The general classification of bauxite rocks based on their chemical structure can be represented in Table 4.^[14–16]

In various types of ores, free aluminum oxide is presented as a trihydrate ($\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$) which is crystallized in monoclinic crystallographic system or a monohydrate ($\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$) which is crystallized in orthorhombic crystallographic system.

Table 4 Minerals commonly found in bauxites

Minerals	Chemical composition
Gibbsite (hydrargillite)	$\alpha\text{-Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$
Baehmite	$\alpha\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$
Diaspore	$\beta\text{-Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$
Hematite	$\alpha\text{-Fe}_2\text{O}_3$
Goethite	$\alpha\text{-FeOOH}$
Magnetite	Fe_3O_4
Siderite	FeCO_3
Ilmenite	FeTiO_3
Anatase	TiO_2
Rutile	TiO_2
Brookite	$\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 3\text{H}_2\text{O}$
Kaolinite	$\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$
Quartz	SiO_2

Silicon dioxide is the main harmful impurity in bauxites. It is present at the form of free silica or as a compound with other elements. In addition, bauxites have the iron in the various forms. Besides the main chemical elements, bauxites contain Ti, S, Li, Cu, Ag, Au, Be, Zn, Sr, Cd, Ba, Sc, rare-earth elements such as B, Ga, Ge, Zr, Sn, Hf, Pb, P, V, Nb, Bi, Cr, Mo, Mn, Co, Ni, and U.

Free moisture in crude bauxite may range from 5% to 30%.^[5] In dried bauxite, most of the free moisture has been removed by heating crude bauxite in rotary drying kilns at about 600°F. Calcined bauxite is heated in the kilns to 1700–1900°F to reduce 1 ton of calcined bauxite.

Cell-grade alumina specifications and typical specifications for grades of bauxite are presented in Tables 5 and 6.

The nepheline rocks are the second most important type of aluminum raw material after bauxites. These rocks contain $\text{Na}[\text{AlSi}_3\text{O}_8]$ mineral. The theoretical composition of nepheline is 35.7% Al_2O_3 ; 42.4% SiO_2 ; 21.9% Na_2O . There are many different types of the nepheline rocks. They are rich with potassium only or with sodium and potassium. Nephelines crystallize in the hexagonal close-packed lattice of the pyramidal class. Normally they can be found as granular and solid mountain mass (massif). As crystals nepheline is seldom found. Usually nepheline has light coloring or it is colorless. Nepheline is rather easily dissolved in mineral acids with SiO_2 forming a gel.^[17]

In spite of that, aluminum in nepheline also contains silicon, the significant contents of alkalis in the composition of this mineral enables the opportunity to reduce from them an aluminum oxide and produce the by-products of sodium carbonate and cement. Usually the nepheline rocks can be found as the mountain masses in combination with alkaline rocks.

Alunite is $\text{KA}[\text{Al}_3(\text{SO}_4)_2(\text{OH})_6]$ belongs to the group of the alkaline double sulfate of aluminum. It is also the important raw material for aluminum production. The chemical composition of this ore can vary significantly. Theoretical composition of alunite is 37.0 wt% Al_2O_3 ; 11.4 wt% K_2O ;

38.6 wt% SO_3 ; 13.0 wt% H_2O . In addition to the compounds above, SiO_2 , CaO and Fe_2O_3 can be present.

Alunite crystallizes in the tetragonal system. Usually it consists of small crystals with grayish, yellowish or reddish color. Due to the potassium and sulfur contents, potassium fertilizers and sulfuric acid can be extracted.

Disthene (kyanite) is a high quality raw material for electrothermal reduction of aluminum. The minerals of this group represent polymorphic modifications of the substance

with the chemical formula of $\text{AlOAl}[\text{SiO}_4]$. Theoretical chemical composition is 63.2% Al_2O_3 and 36.8% SiO_2 .

Disthene crystallizes in the triclinic lattice. Most frequently disthene crystals have light-blue, grayish-blue, least often yellow or brown color and glassy glance. Anisotropy of hardness and coloring were noticed on disthene crystals. So on a plane (100) in a direction $\langle 100 \rangle$ hardness is equal 4.5 and along a direction (010) is 7.0. Coloring along the base plane is olive-green, and through lateral planes is reddish-brown.

Table 7^[8] summarizes the basic differences of the three fundamental forms of bauxite which occur, namely gibbsite, bahmte and diaspor. It is seen that the latter two are in the monohydrate form, whereas the former is a trihydrate. The two monohydrate forms give rise to different structural forms of alumina on rapid dehydration, while they also exhibit different solubilities in caustic soda. Gibbsite dissolves much more readily. In caustic soda (having a higher solubility as well as dissolving faster), but it has a lower intrinsic alumina content. The conditions for the dissolution of the alumina hydrate will vary for the different structural forms, and also depend on caustic soda concentration and temperature.

Many of the deposits currently being mined have a dominance of gibbsite (trihydrate), but they often have a significant proportion of a monohydrate crystalline form also.

Table 5 Cell-grade alumina specifications, in weight-percent

Impurity	Maximum content	Impurity	Maximum content
SiO_2	0.015	B_2O_3	0.001
Fe_2O_3	0.015	TiO_2	0.002

Density, g/cm^3	2.42	3.01	3.44
Temp, for rapid dehydration ($^{\circ}\text{C}$)	150	350	450
Solubility of Al_2O_3 (g/l) in 100 g/l	105	45	Virtually
Na_2O aqueous solution at 125°C			insoluble

Therefore, the chemical processing must be a compromise between the optimum conditions for each of the two types. This is particularly so for the extensive bauxites occurring in the northern area of Australia—which is the main supplier for the present world market.

As already mentioned, the main impurities are compounds of iron, silicon and titanium. The iron compounds occur chiefly in the form of haematite (Fe_2O_3), siderite (FeCO_3) and goethite ($\text{FeOOH}\cdot n\text{H}_2\text{O}$). The silicon compounds occurs in the various structural forms of quartz as well as hydrated double salts with alumina such as kaolinite and halloysite ($\text{Al}_2\text{O}_3\cdot 2\text{SiO}_2\cdot 3\text{H}_2\text{O}$). Generally titanium occurs in, the form of rutile (TiO_2), but it can also be present in small amounts as ilmenite or anatase. The compounds of iron and titanium are insoluble in caustic solutions and therefore present no problem for the selective dissolution of the aluminum oxide. The silicon occurring as quartz does not present a serious problem either, since it has only a limited solubility in the caustic soda solution used. This contrasts with the combined forms (kaolinite and halloysite) which readily c solution. The dissolution of silica leads to a reduction in the yield of the extracted alumina, and therefore the soluble desirable. Consequently the silica content is usually referred to as reactive or unreactive, depending on its tendency. Table 8 summarizes a range of compositions predominantly containing gibbsite.^[8]

REDUCTION OF ALUMINUM

Modern-day aluminum production involves two independent industrial processes for the transition from the naturally occurring aluminum oxide ores to the extracted metal (Fig. 6).^[18] The reduction of aluminum oxide to aluminum includes two main stages:

- Production of an aluminum oxide (alumina) from aluminum ores. It can be done by different chemical methods.
- Production of aluminum from an aluminum oxide by electrolysis with fused sodium aluminum fluoride (Na_3AlF_6) commonly called cryolite.^[6,8,14,18–20]

Production of Aluminum Oxide from Bauxites

The Bayer Process

All commercially produced alumina from bauxite is obtained by a process patented by Karl Bayer in 1888 (German Patent 43,977). The Bayer process involves a caustic leach of the bauxite at elevated temperature and pressure, followed by separation of the resulting sodium aluminate solution and selective precipitation of the aluminum as the hydrated aluminum oxide ($\text{Al}_2\text{O}_3\cdot 3\text{H}_2\text{O}$).

Alumina (aluminum oxide) is white powder produced from bauxite ores by treating them with caustic soda in the Bayer process (Fig. 7).^[8] The actual processing conditions such as the leach temperature, holding time, and caustic concentration, as well as the costs, are influenced by the type of bauxite to be processed.

As a result, a Bayer alumina plant is designed to treat a specific bauxite and cannot use a bauxite that is too different from the one the plant was designed to use, without major plant modifications.^[3]

The Bayer process is initiated by mixing crude bauxite with preheated spent leach solution. Lime is added during this initial step to control the phosphorus content and to increase the solubility of alumina. The resulting slurry, containing 40% to 50% solids, is pumped with additional caustic leach solution to pressurized digesters where high-pressure steam is used to raise the temperature. Alumina and some of the silica are dissolved during this step, soluble sodium aluminate is formed, and a complex sodium aluminum silicate is precipitated.

The technological scheme of the Bayer bauxite processing method consists of several operations. Bauxite coming from a mine is dried, and progressively crushed. Then it is placed into an autoclave with a NaOH solution at 230°C and higher than atmospheric pressures.

Digestion, in tanks 10–15 ft in diameter and up to 90 ft high, takes up to 5 hr. Leaching temperatures range from about 140°C to about 323°C, with corresponding pressures ranging from about 60 psi to over 1000 psi. The lower temperature ranges are used for bauxites in which nearly all of the available alumina is present as gibbsite.

Table 8 Typical compositions from different bauxite deposits (in weight %)^[8]

Oxides*	African Gold Coast	British Guyana	Darling Ranges (Western Australia)	Greece	Weipa (Australia)
Al_2O_3	55.2	61.1	30–35 available	60.2	57.0

Fig. 6 Flow-sheet for aluminum production from alumina

Fig. 7 The flow-sheet of the Bayer process

The higher temperature is needed to digest bauxite having a large percentage of baehmite. Caustic concentration of the spent leach solution, expressed as grams per liter of sodium carbonate (Na_2CO_3), averages about 200 g/l for gibbsitic bauxite and about 300 g/l for bauxites with a high baehmite content.

Bauxites arrive on chemical processing without the preliminary mechanical enrichment. This process involves digesting bauxite at high temperatures with caustic soda which dissolves the alumina leaving iron oxide and silicates as waste products (red mud). This is accomplished by the following chemical reaction

The resulting slurry of sodium aluminate solution and insoluble red mud from the digesters is cooled to atmospheric boiling temperature, and a coarse sand waste fraction is removed by gravity separators or wet cyclones. The fine solids in the red mud are then separated by decantation of the overflow in setting tanks measuring about 15 ft in depth and 50–125 ft in diameter.^[3]

The clarified sodium aluminate liquor is cooled until it becomes supersaturated, then seeded with fine crystals of alumina trihydrate. The alumina is precipitated as the trihydrate, separated by sedimentation or filtration, and washed. The spent leach solution containing caustic soda is regenerated in the precipitation step, and together with the alumina remaining in solution, is recycled to the digesters. The filtered and washed alumina trihydrate is calcined for use in making metal.

Two forms of calcined alumina are used to produce aluminum. European Bayer plants have traditionally produced a fine-grained highly calcined, floury alumina while North American Bayer plants have always produced a coarser grained, porous, sandy alumina that has not been totally calcined to the alpha alumina. The red mud contains Fe_2O_3 , TiO_2 , the sodium aluminosilicate, and a small quantities of other metal oxides. Because the complex represents a loss of both alumina and soda a low reactive silica content in the bauxite is desirable. The loss of soda is made up by adding caustic soda or soda ash and lime to the spent leach solution to bring it up to the appropriate caustic concentration before it is recycled.

The liquor is washed out and is separated from the red mud. The liquor is filtered and then a small amount of aluminum hydroxide is introduced and slowly mixed. As a result, aluminum oxide is precipitated, from the aluminate solution.

The precipitated trihydrate (aluminum hydroxide) is filtered and is then calcined in a rotary kiln at 1200–1300°C to remove the water of hydration and to leave the alumina in a form suitable for use in the electrolytic production of aluminum.

Invariably, the alumina prepared by the Bayer process has small amounts of impurities associated with it and typical impurity levels are summarized in Table 9.^[8]

Variations in impurity levels will occur with different ore types, but the values show that a fairly high quality material is produced in the Bayer process. Some of the sodium oxide will be as sodium aluminate, and the small

amounts of calcium oxide are present by virtue of the technology used to reconstitute the sodium hydroxide liquor for the extraction stage. This method is used for processing of high quality bauxites only.

The Production of Alumina from Bauxites with the Higher Silicon Content

The production of alumina (aluminum oxide) from bauxites with the higher silicon content (from 8% to 15% silica) and other inclusions from aluminum raw materials is carried out by the agglomeration.^[14,18] This combination process has been developed by Alcoa. In this process, the bauxite is mixed with the limestone and the sodium carbonate. The mixture agglomerates in rotary furnaces at 1200–1300°C. In the agglomeration process the sodium carbonate reacts with aluminum oxide forming the sodium aluminate:

The received aluminum oxide is crushed and leached by water or a soda solution. As a result aluminum passes into a solution. The non-soluble red mud is separated from it. Then a solution free from silicon dioxide is produced by heating with a lime in an autoclave at 160°C. The silicon dioxide precipitates out as non-soluble calcium silicate (white mud). The calcium silicate is separated from the liquor by filtration. The resulting liquor precipitates aluminum hydroxide by passing carbon dioxide through the liquor:

Formed aluminum hydroxide has been separated by filtration, then washed out and calcined for alumina production. Extraction alumina by an agglomeration method accounts for 90% of total alumina products. A portion of the washed alumina may be left in the trihydrate form for chemical uses or it may be further processed under controlled conditions to produce a variety of chemical alumina, such as activated or tabular alumina for uses other than metal production.

The Combine Method (Bayer Process with Agglomeration)

For processing high silicon content bauxites sometimes, it is expedient to apply a combination of a Bayer process with the method of agglomeration.^[8] The combination of the Bayer process and agglomeration process improves the technological cycle of processing bauxite and enables the use of low quality bauxites.

In the former Soviet Union, alumina is extracted from nepheline $[(\text{Na}, \text{K})\text{AlSiO}_4]$ flotation concentrates and other non-bauxitic materials containing about 30% alumina. Nepheline syenite has been mined at Belogorsk in Siberia and obtained as a byproduct of apatite recovery from syenite deposits in the Kola Peninsula.

Table 9 Typical impurities in commercial hydrated and calcined alumina^[8]

Impurity	Percentage impurity Dried alumina trihydrate	Normal calcined alumina
SiO_2	0.020	0.03
Fe_2O_3	0.015	0.02
Na_2O	0.250	0.50
CaO	0.030	0.05
Loss on ignition	34.700	0.80
Moisture (free)	0.400	—

Processing Method for Alumina from Nepheline

The processing method for alumina from nepheline ores consists in the agglomeration of a charge comprised of nepheline concentrate and limestone into the rotating furnaces at the temperature of 1280–1310°C.^[8,18] Calcium oxide of limestone reacts with nepheline. A cake consisted of bicalcium silicate and sodium aluminate is formed. A cake is leached by the sodium-alkali-aluminate solution which sodium and potassium aluminates pass into. Formed at the carbonization, aluminum hydroxide drops out into a deposit, and sodium carbonate and potash remain in a solution.

Filtered and calcined aluminum hydroxide is a final product from which pure aluminum is extracted from. The process of extraction makes about 80% of Al_2O_3 .

Historically, a small tonnage of alumina has been extracted commercially in Norway from high-iron bauxites by the Pedersen process. In this process, bauxite, limestone, coke, and iron ore are smelted in an electric furnace to produce pig iron and calcium aluminate slag containing 30% to 50% alumina. The slag is leached with sodium carbonate solution, and alumina trihydrate was precipitated by carbon dioxide. During World War II, the process was also used at a Swedish plant to treat andalusite (Al_2SiO_5).

The Pechiney H-Plus Process

In Europe, the major development has been the process called the Pechiney H-Plus process. Developed by Pechiney in France the process consists of sulfuric acid leaching of the raw material, hydrochloric acid addition to the leach liquor and crystallization of $\text{AlCl}_3 \cdot 6\text{H}_2\text{O}$ by saturation of the leach liquor with gaseous HCl .^[21] The aluminum trichloride precipitate is purified by dissolution and reprecipitation. The final product is calcined to form alumina and to produce HCl for recycle. Successful laboratory scale development has been followed by a pilot plant operation at 15–20 tons Al_2O_3 per day scale at Marseilles. According to Cohen and Mercier,^[22] the alumina so produced has a higher purity than alumina produced from bauxite by the Bayer process. The process flow-sheet is shown in Fig. 8. An analysis of the potential economics of the process indicated that, with heat recovery, the total operating cost to produce alumina from coal shale would probably be 1.15–1.4 times the cost of production from bauxite at 1978 bauxite and energy prices.

Technology for the Recovery of Metallurgical-Grade Alumina from Coal Ash

Large quantities of coal ash are produced in the United States every year by coal-burning power-plants. In 1975,

this amounted to 60 million tons, of which 42.4 million tons was boiler slag.^[23] (Fly ash is the fine material that is carried out of the boiler with the stack gases and is collected by precipitators. Bottom ash is coarser material that falls through the grate, and boiler slag is the molten as that collects at the bottom of slag tap boilers.)

Fly ash, bottom ash, and boiler slag all contain significant amounts of Al_2O_3 and therefore can be considered as potential sources for the production of metallurgical-grade Al_2O_3 . Typically, fly ash contains from 15% to 30% SiO_2 , 50% Fe_2O_3 , up to 20% Al_2O_3 , with the remainder containing alkali and alkaline-earth oxides plus some unburned carbon.^[24] Fly ash cannot be considered a high-grade potential source of metallurgical-grade Al_2O_3 when compared with the large reserves of kaolinitic clays (35–40% Al_2O_3) and anorthosite (25–30% Al_2O_3).^[25]

Considerable economic benefit would result if fly ash could be physically beneficiated to upgrade its Al_2O_3 content before being processed by extractive metallurgical technique. A form of beneficiation that has been studied is magnetic separation. Scientists in the former Soviet Union have applied this technique to the ashes from a coal-gasification plant to produce a nonmagnetic fraction containing greater than 30% Al_2O_3 .^[26]

Table 10 shows the calculated costs in the United States as of late 1976 to produce 1 ton of Al_2O_3 .

Of the three general methods (alkaline-sinter process, acid-leach process, chlorination processes) examined for recovering metallurgical-grade Al_2O_3 from coal ash, sintering (lime or lime-soda) offers the most short-term potential. It has been demonstrated that Al_2O_3 can be produced by this procedure, and the incorporation of a desilication step would possibly produce a grade of Al_2O_3 acceptable to the aluminum industry. The major unresolved problem with lime sintering is economic. Coal ash is basically a low-grade source of Al_2O_3 , and the reagents and operating costs to conduct a high-temperature sintering operation are high. To be economically viable, the production of Al_2O_3 from coal ash by a sintering process should be integrated with cement production.

Direct acid treatment of coal ash does not appear promising. Some form of pretreatment of the ash, such as reaction with limestone during power generation, may provide a means to improve the yield of Al_2O_3 during acid leaching.

Dry chlorination of coal ash at high temperature is interesting because of the effective conversion of the aluminum values of AlCl_3 . Dry chlorination expensive in money and energy to decompose.^[27]

Production of Commercial Purity Aluminum

Primary aluminum is produced by the reduction of alumina by electrolysis in a molten bath of natural or synthetic cryolite (Na_3AlF_6), which serves as an electrolyte and a solvent for the alumina.

Fig. 8 Flow-sheet of the Pechiney H-Plus process

Table 10 Calculated costs in the U.S. to produce 1 ton of alumina^[27]

Material	Cost per ton, U.S Dollars	Process cost, U.S Dollars	
		Fly ash	Bauxites
Bauxite	16.00	—	41.32
Fly ash	—	—	—

Electricity	(*)	16.50	1.08
TOTAL		167.38	70.11

*Cost of electricity was \$0,015 per kilowatt-hour.

Electrolytic Reduction (Smelting)

Commercial purity aluminum is manufactured mainly by electrolysis.^[28–32] The process used for the electrolytic reduction of alumina to the metal does not differ fundamentally from the original process devised in 1889 by Hérŭlt and Hall. The main change being an increase in the size of each electrolytic cell.^[33]

Primary aluminum production is electricity-intensive. The current U.S. average energy consumption for aluminum reduction is estimated to be 15.18 kWh/kg of aluminum. The lowest energy consumption that can be achieved today is about 13.0 kWh/kg of aluminum for a line of modern, high-amperage reduction cells. Production cells normally have current efficiencies ranging from 85% to 95%. Large, modern reduction cells operate with current efficiencies of 94–96%.^[34]

Fig. 9 is a diagrammatic section of a multi-anode furnace from which the main points of construction can be seen. The outer casing consists of a brick-lined rectangular

Fig. 9 Schematic diagram of an electrolytic cell fitted with a "Soderberg" anode

steel box which acts as container and support. Inside this box the cathode is constructed of baked carbon or graphite blocks, cemented together with a paste of ground coke and pitch, and of such a shape as to contain the bath of electrolyte. The electrolyte is largely molten cryolite or with additions of calcium fluoride and aluminum fluoride are made and alumina. A typical composition of this solution consists of cryolite 75–90%, alumina 2–8%, aluminum fluoride up to 10%, calcium fluoride 5%.

The anode consists either of a number (as many as twenty) or pre-baked carbon blocks dipping into the molten electrolyte, or of a single massive Saderberg electrode. Although there are two fundamental designs of anodes used in industrial aluminum electrowinning, they are both formulated from similar materials and undergo the same type of reactions within the operating cell. For environmental reasons, there has been an increasing tendency to move to the "pre-baked" anodes, and therefore the presentation of data and discussion of reactions will be biased towards this form of anode. The Saderberg type of electrode uses the waste heat of the furnace to bake the anode paste in situ instead of this being done as a separate operation as with the pre-baked anodes.

Electrolysis of Aluminum Oxide (Fig. 9) Aluminum oxide Al_2O_3 dissolves in molten cryolite Na_3AlF_6 at the temperature of 950–970°C^[7] and break down electrochemically by discharging aluminum cations on the cathode (the molten aluminum), and the acid-containing ions (oxygen ions)—on the graphite-carbonic anode. The molten cryolite dissociate on ions Na^+ and AlF_6^{3-}

and aluminum oxide—on complex ions AlO_2^- and AlO^+ :

which are in balance with the simple ions:

The reduction of trivalent aluminum is the predominant process occurring at the cathode:

In addition the incomplete discharge of the trivalent aluminum with the formation of univalent ions can take place: $\text{Al}^{3+} + 2e \rightarrow \text{Al}^+$ and discharge univalent ions with settling of the metal:

At the graphite anode there is the discharge of oxygen ions. The oxygen oxidizes carbon of the anode and is released as a mixture of $\text{CO}_2 + \text{CO}$.

The primary aluminum (raw aluminum) taken from an electrolyzer contains three groups of impurities: a non-metallic (fluorine salts), such as α - and γ -aluminum oxide, aluminum carbide and aluminum nitride, and graphite particles; metallics such as iron and silicon passing from raw materials, coal materials and structural electrolyzer elements; and gaseous—mainly hydrogen formed as a result of electrolytic water dissociation.

For simultaneous aluminum purification from non-metallic impurities and hydrogen, the filtration through a fluxing filter with the adding blowing nitrogen is applied. As a result of such purification the contents of hydrogen in aluminum is reduced from 0.22 down to 0.16 cm³ on 100 g of metal.

The most effective method of simultaneous purification of aluminum from sodium, hydrogen and non-metallic impurities, is by bubbling a gas mixture of nitrogen with 2–10% Cl through the molten metal. This method of purification permits a lower sodium content of 0.0003–0.001% at the total consumption of a gas mixture from 0.8 up to 1.5 m³/g of the metal.^[32]

Future Developments in Hall-Héroult Cells With the gains in productivity and cost reductions achieved over the past decade allowing aluminum to remain a competitive

commodity metal and meet the growth in world demand of 2–3% per year, the primary aluminum industry has become complacent in searching for alternative processes. Intellectual energy has been focused on cost cutting and environmental concerns.^[43]

Inert anodes have been the dream of aluminum producers from the beginning, and numerous materials have been tried. But there are no really inert materials so far. In the cathode, prolonged cell life, a lower cathode voltage drop, stability over time, and more resistant sidewalls are needed. While a 1300 day life was acceptable 50 years ago, and 2000 day lives are acceptable today, cathode lives of more than 3000 days will be demanded in the future. With the rise in use of graphitic blocks to decrease the cathode voltage drop, improved abrasion resistance is a necessary challenge. One solution is a coating with TiB_2 .^[43]

There are significant efforts to develop transition stable wetted cathodes and nonconsumable anodes. It looks as if aspects of designs for retrofitted cells and advances in material science will be resolved in industrial tests by 2005. In 1997, the Aluminum Association and the U.S. Department of Energy joined forces to fund further the search for materials for the inert anodes. From the present perspectives, meaningful pilot bipolar cells for liquid aluminum could be in progress by 2010 at the earliest.^[43]

There are challenges remaining in the section and management of the lining of the reactor. Even when the pure CO evolved in this process is reconverted to electrical energy, there is twice as much CO_2 evolved as for the electrolytic process, although the unit energy is lower.

Perhaps an alternative approach in extracting aluminum in the liquid state could derive from what is being discovered about slurry electrolytes. In this method, solid aluminum, even if dendritic, could be electrodeposited on a rotating disc cathode from a low melting (540–600°C) all-fluoride electrolyte using a nonconsumable anode. The solid aluminum would be removed within the fully enclosed cell and transported to a melting furnace above 660°C where the solid aluminum and entrapped bath would be separated. In this concept, the bath is recycled to the cell, and the now-liquid aluminum processed conventionally.^[43]

The ALCOA Chloride Process

In January 1973 ALCOA^[35] announced the development of a new aluminum electrolysis process. The process employs electrolysis of aluminum chloride dissolved in alkali and alkaline earth chloride melts. Among the most favorable aspects of the process are reduced electrical energy consumption (~30%), less pollution and more flexible operation.

The first step of the ALCOA process is the production of very pure alumina by the Bayer process. The two succeeding steps are the chlorination of alumina and the electrolysis of the dissolved molten aluminum chloride.

The resulting aluminum chloride is purified by passage through a special filter before resublimation in an inert gas. The alumina is then transported to a tank where it is stored in the crystalline state. The cell used for the electrolysis consists of a steel mantle lined with a thermally insulating, non-conducting refractory material which is not corroded by the electrolyte.

The total energy consumption of the process depends on the raw materials used, e.g. bauxite versus pure alumina and petroleum coke versus carbon coke.

While the Hall-Heroult process has its fluoride emission problem, the chlorination steps in the ALCOA process may result in chlorinated hydrocarbons being formed. The economic potential for this process is strongly dependent on the cost of producing AlCl_3 in the chlorination step.

The advantages of the ALCOA method is compared with electrolysis of the kryolite-aluminum oxide melt (Al_2O_3 dissolved in cryolite Na_3AlF_6) are: energy saving up to 30%; an opportunity of application Al_2O_3 with the higher silicon content; substitution of cryolite by cheaper salts; reducing or completely eliminating the problem of fluorine liberation.

The Toth Process

This process is based on reduction of AlCl_3 by Mn and bears the name of its inventor Charles Toth. Since 1968 the process has been described in several patents^[24] and also has received considerable publicity in the financial and engineering press. The Toth process comprises four major steps:

Step 1: at the temperature of 925°C:

Step 2: at the temperature of 230°C:

Step 3: at the temperature of 600°C:

Step 4: at the temperature of 1750°C:

The total reduction considered being:

Toth process is an indirect carbothermal reduction of alumina. Several types of cheap minerals with Al_2O_3 contents as low as 30–40 wt%, for instance kaoline labradorite and bauxite, are potential raw materials.

Beside the potential use of low grade ore, the really favorable aspect of the Toth process is its presumably low demand of electrical energy, i.e. 5% of the Hall-Heroult process according to the inventor. It must be recognized, however, that the appreciable reduction in electrical energy is largely compensated by an increased carbon consumption.

A successful large-scale operation of the Toth process still remains to be demonstrated and considerable work has to be done before the final answer to its potential can be given.

Aluminum Extraction from Anorthosite by Leaching with Hydrochloric Acid and Fluoride

The United States is more than 90% dependent on imported bauxite as a source for aluminum, but it has vast non bauxitic aluminum resources, such as kaolinite, anorthosite, alunite, etc. To reduce this dependence, the Bureau of Mines conceived a raw materials-process technologies matrix as a means of systematically investigating the technology options available for processing domestic aluminum resources.^[36] Resources considered were clay, anorthosite, alunite, dawsonite contained in oil shale, and coal as and coal shale.^[25,37]

Most of the research on alumina recovery from anorthosite was concentrated on the lime-soda-sinter process.^[38] Anorthosite is sintered with soda ash and limestone. Leaching, desilication, and precipitation steps are performed before alumina is recovered as the trihydrate. The lime-soda-sinter process has two major drawbacks:

- In addition to mining anorthosite, large amounts of limestone and soda ash are required.
- Sintering is performed at 1300°C, which consumes appreciable amounts of energy.

Another method for recovering alumina from anorthosite is the melt-quench technique^[39] in which a charge of anorthosite is arc melted at approximately 1650°C and then rapidly cooled. The resulting amorphous product is amenable to alumina extraction by acid. Because of their crystalline structure, aluminum silicates, such as anorthosite, are not readily attacked by a mineral acid unless the crystalline structure is altered. Acid in conjunction with the fluoride ion disrupts the silicate structure sufficiently so that acid leaching is effective in extracting the aluminum content.

Anorthosite is a rock composed mainly of calcium-rich plagioclase. Anorthosite resources of the United States are estimated at 599 billion tons averaging 27% Al_2O_3 .^[25] Large anorthosite deposits are located in Minnesota, New York, Wyoming, and California. Chemical analysis of the anorthosite is the following: 29.3% Al_2O_3 , 2.0% Fe_2O_3 , 11.5% CaO , 0.15% TiO_2 , 51.4% SiO_2 , 5.1% Na_2O , 0.29% K_2O , 0.26% MgO .

Excellent aluminum extractions were obtained from Wyoming anorthosite by countercurrent leaching with hydrochloric acid and fluoride ion. The model (Fig. 10) schematically illustrates simulated three-stage countercurrent leaching by a series of batch tests. Fresh HCl leachant moves downwards; anorthosite ore moves to the right. The two upper rows prepare leaching acid for use in the bottom row, where ore is contacted by acid of increasing strength. Since the spent liquors from the initial first and second rows are not utilized in the stages immediately below, they are discarded. Fluoride was added to the fresh leaching acid. H_2SiF_6 , Na_2SiF_6 , and CaF_2 were used as sources of fluoride, and at equivalent amounts of fluoride addition no difference was noted in their effect. Retention time for each stage was 2 h, or a total leach time of 6 h.

The leaching process eliminates the energy-intensive step of high-temperature calcination. Countercurrent leaching resulted in a more efficient use of acid and fluoride than single-stage leaching. Ninety percent of the aluminum values were extracted with 95% of stoichiometric HCl requirement and a F/Al ratio of 0.27. If acid concentration is increased, the fluoride addition can be decreased.

Alternative Methods of Production

Despite several disadvantages, the electrolytic method for the production of aluminum is still the only process practiced on an industrial scale. The main drawbacks are:

- the very large size of the economic unit
- the employment of low voltage D.C. as a source of energy
- the additional capital investment in the alumina factories

Continued efforts have been made to devise a process that would be free from these problems, and recently a certain amount of progress has been made. It is comparatively simple to reduce crude bauxite in an electric furnace with carbon, but the result is an alloy of aluminum with iron and silicon, which must be purified. Two methods are available: in one the aluminum is dissolved in a suitable solvent, e.g. Zn, Mg, or Hg, the impurities filtered off, and the solvent recovered by distillation, in the other, which has been operated on a pilot scale in Canada, the aluminum is volatilized as a sub-halide. The Al-Fe-Si alloy is treated with aluminum chloride at 1000–1200°C at atmospheric pressure. The resulting sub-chloride, AlCl , is passed to a condenser where the aluminum is deposited according to the reaction:

The aluminum chloride is recycled.

Another method which has reached pilot plant stage in France depends on the reduction of pure alumina with carbon, and instead of capturing the aluminum vapor in another metal and so obtaining an alloy, the vapor is

Fig. 10 Diagram of simulated, three-stage countercurrent leaching

captured, and re-oxidation prevented, with aluminum carbide. The two reactions

and

proceed simultaneously, and under the right conditions at 2400°C an alloy of aluminum and the carbide is obtained which may contain as much as 80% aluminum. This, on cooling, deposits the carbide, which can be separated by fluxing with fused chlorides. The carbide is recycled.

None of these methods saves energy in comparison to the electrolytic method, but they do open up the possibility of working smaller units, with lower capital investment.

PRODUCTION OF SUPER PURITY ALUMINUM (REFINEMENT)

The production of superpurity aluminum, 99.99+% purity, requires special procedures, such as a continuous electrorefining of commercially pure aluminum in a Hoopes cell.

The electrolytic refinement of aluminum carries out by the three-layer method.^[7,19,40] For this purpose there are three layers available into the electrolyzer (Fig. 11). The bottom layer serves as the anode. It represents a refined (purified) aluminum alloy with copper. Copper is introduced to increase the density of a layer. An average density layer is the molten electrolyte. Its density is less than the density of an anode alloy and higher than one of purified (cathode) aluminum which is above an electrolyte (a molten top layer).

At anode dissolution more electropositive impurities than aluminum such as Fe, Si, Ti, Cu, and other, remain in

an anode alloy. Aluminum is dissolved only at the anode. It goes into electrolyte in the form of metal ions Al^{3+} :

During the electrolysis, ions of aluminum are transferred to the cathode:

As a result, a layer of the molten purified aluminum is accumulated on the cathode.

More electronegative impurities than aluminum such as Ba, Na, Mg, Ca can be dissolved electrochemically on the anode. These ions report to the electrolyte. Because of the small amount of electronegative impurities in the raw aluminum they have not accumulated to a great extent in the electrolyte. The discharge of these ions on the cathode does not practically occur because their electrode potential is more electronegative than aluminum.

The fluoride-chlorine electrolyte is more common for this process. The chemical composition of it is 55–60% BaCl_2 , 35–40% $\text{AlF}_3 + \text{NaF}$ and up to 4.0% NaCl . Mole ratio NaF/Al_3 is 1.5–2.0; The melting point of the electrolyte is 720–730°C. The temperature of the electrolysis is approximately 800°C. The electrolyte density is 2.7g/cm³.

The anode alloy is prepared from the primary aluminum and pure copper (99.90–99.95% Cu) which is introduced into the metal in quantity of 30–40%.^[7] The density of a liquid anode alloy of such composition is 3.0–3.5 g/cm³. Density of pure molten cathode aluminum is 2.3 g/cm³. Purity of aluminum refined by the three-layer method is 99.95%. Purity is determined based on the quantity of five main impurities such as Fe, Si, Cu, Zn, Ti.

On evidence derived from^[6] refined aluminum has the following composition: Fe – 0.0005–0.002%;

Si – 0.002–0.005%; Cu – 0.0005–0.002%; Zn – 0.0005–0.002%; Mg – traces; Al – other. Refined aluminum usually processes into a semi-finished product of the specified above composition or alloyed by magnesium.

Production Extreme Purity Aluminum

Zone Melting

The principle of zone melting consists of repeated passing of a melted zone along an aluminum ingot.^[7] The impurities decreasing the melting point aluminum at the zone melting are concentrated in the molten zone and are transferred to the end as an ingot. These impurities are Ga, Sn, Be, Sb, Ca, Th, Fe, Co, Ni, Ce, Te, Ba, Pt, Au, Bi, Pb, Cd, In, Na, Mg, Cu, Si, Ge, Zn. The impurities increasing the melting point are concentrated in a solid (initial) part of an ingot. These impurities are Nb, Ta, Cr, Ti, Mo, V. The impurities such as Mn and Sc do not change the melting temperature of aluminum and are not removed at the zone melting.

Aluminum has significant chemical activity. Therefore, zone melting should be carried out in a vacuum or in an atmosphere of inert gas (argon or helium). During the zone melting in a vacuum, extreme purity of aluminum can be achieved because some impurities “volatilize.” Typical elements that volatilize are Mg, Zn, Cd, alkaline and alkaline-earth metals.

By zone melting with several consecutive cycles, it is possible to achieve very pure aluminum.^[41] The initial material of each new cycle is the purest part of an ingot received at the previous cycle. The purity of received aluminum is determined based on the difference of the main impurities such as Si, Fe, Mg, Mn, Ti, Cu, Cr, Zn, Na, V making up more than 99.9999%.

Another method of achieving extreme purity aluminum is refined electrolysis of pure or commercial pure aluminum.^[6] Complex aluminorganic aluminum compounds are applied as the electrolyte. Electrolysis does at 100°C between solid aluminum electrodes. The composition of electrolyte can differ. For example, in^[42] electrolysis of 50% solution of $\text{NaF} \times 2\text{Al}(\text{C}_2\text{H}_5)_3$ in toluene is applied. Using this method, the metal purity of 99.999–99.9999% can be achieved.

Ionic Liquids in Surface Protection of Aluminum and Its Alloys

Joaquín Arias-Pardilla, Tulia Espinosa, José Sanes, Ana Eva Jiménez, Ginés Martínez-Nicolás, and María Dolores Bértudez

Department of Materials Engineering and Manufacturing, Universidad Politécnica de Cartagena, Cartagena, Spain

Abstract

Aluminum and its alloys are used in an increasing number of applications but the development of surface coatings and new techniques for corrosion resistance enhancement and for increasing wear resistance will be determinant for applications under aggressive environments. Ionic liquids have already found many industrial applications, including their use in surface protection. The present article will focus on the use of ionic liquids in aluminum and its alloys surface protection applications, including corrosion protection and inhibition, anodization and passivation processes, wear resistance, and potential applications of ionic liquid electrolytes in energy storage devices.

Keywords: Aluminum; Anodization; Corrosion protection; Ionic liquids; Passivation; Surface protection.

INTRODUCTION

Aluminum and its alloys are used in an increasing number of applications.^[1] The growing interest in aluminum alloys is based not only upon their high specific properties but also on their high thermal and electrical conductivities, and their ease of processing. Other characteristics such as the possibility of applying different surface treatments and finishing processes, their good corrosion resistance, and their recyclability make them the materials of choice in such strategic sectors as transport, aeronautics, electronics, etc.

One of the main weaknesses of aluminum alloys continues to be their poor tribochemical performance due to their low surface hardness and their high reactivity under conditions of severe abrasive wear. The development of surface coatings and new techniques for corrosion resistance enhancement and for increasing wear resistance will be determinant for applications under aggressive environments. This is particularly so for the series of aluminum alloys that present higher reactivity as is the case of aluminum-copper, widely used in aircraft or automotive parts.

Ionic liquids are liquid salts at room temperature, which are formed by a bulk organic cation and an organic or inorganic anion (Fig. 1). Although there exist millions of theoretical combinations of anions and cations, some of the most commonly studied species contain ammonium, phosphonium, imidazolium, or pyridinium cation moieties, while a variety of anions have been used.

Many of them contain boron, sulfur, phosphorus, and fluorine in their formulations, as tetrafluoroborate, methyltrifluoroborate, trifluoromethyltrifluoroborate hexafluorophosphate, trifluoromethanesulfonate (pentafluoroethyl), trifluorophosphate, etc.

The unique physicochemical characteristics of ionic liquids make them suitable for many industrial applications in fields such as synthesis, catalysis, electrochemistry, separation technology, and materials science including their use in surface protection.^[2] Their high electrochemical window and stability allow the electrodeposition of metals with very low negative potentials, including electroplating of aluminum on other metallic substrates using ionic liquid electrolytes.^[3] Kosmus et al.^[4] has demonstrated using mass spectrometric detection that no degradation products are found when a mixture of AlCl_3 and 1-ethyl-3-methylimidazolium chloride is used as an electrolyte for aluminum electroplating.

On the other hand, their high thermal stability, negligible vapor pressure, and miscibility with water and with organic solvents have attracted a high attention in the field of lubrication. In this field, the use of ionic liquids as lubricants or lubricant additives can enhance the wear performance of the aluminum alloys due to the reaction of the ionic liquid anions with the aluminum surface and the formation of tribolayers.^[5]

Therefore, ionic liquids are finding a growing number of applications in aluminum-related technologies, ranging from electrodeposition to refining, lubrication, and recycling processes. In this article, we will review

Fig. 1 Some of the most widely studied ionic liquid cationic and anionic moieties

the use of ionic liquids in aluminum surface protection applications, including corrosion protection and inhibition, anodization and passivation processes, and ionic liquid electrolytes in energy storage devices showing better corrosion behavior.

IONIC LIQUIDS IN ALUMINUM CORROSION PROTECTION

The use of ionic liquids as corrosion inhibitors of aluminum and aluminum alloys was suggested by Uerdingen et al.^[6] when an aluminum–magnesium alloy showed a very low corrosion rate (0.03 mm·year⁻¹) in the presence of imidazolium ionic liquids containing different anions, such as ethylsulfate, octylsulfate, tosylate, and dimethylphosphate, especially in the absence of water. The addition of a 10% of water gave mass loss values under 0.1 mm·year⁻¹.

Long immersion corrosion tests for the Al-Cu 2011 alloy in different imidazolium and pyridinium derivatives with 2–8 chain length substituents and different anions such as tetrafluoroborate, triflate, hexafluorophosphate, tosylate, and bis(trifluoromethanesulfonyl)imide for 30 days, and also in aqueous solutions with 1 wt% or 5 wt% concentration of ionic liquids were performed.^[7] In pure ionic liquids, the Al-Cu 2011 alloy showed no mass loss, and only in the case of the triflate salt, some deposits composed of aluminum oxide, fluorine, and sulfur were observed. In the presence of water, corrosion rate was greatly increased due to hydrolysis of the anion.

Ionic liquids have shown their ability to form protective layers over different kinds of metallic substrates such as gold,^[8,9] lithium,^[10,11] magnesium,^[12–14] copper,^[6,15] steel,^[6,16] and the alloys of these materials, and also over aluminum and aluminum alloys through adsorption on the surface or passive layer formation depending on whether electric potential is applied.

Initially, ionic liquids were used as electrolytes during the electrochemical deposition of metallic films.^[3,17,18] The formation of a passive layer on freshly electrodeposited aluminum from a solution of AlCl₃ in the air- and water-stable ionic liquid 1-butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl)imide has been described.^[19] This passive layer, composed of Al-[bis(trifluoromethylsulfonyl)imide] compounds, hinders electro-oxidation, so that high positive potentials are required to induce attack on the passive film by chloride anions.

Ionic liquids have also been used as corrosion inhibitors, adding a small concentration to a corrosive media in contact with aluminum. Three different alkylimidazolium chlorides with different side chain length substituents were tested as corrosion inhibitors of aluminum in hydrochloric acid solution (1 M HCl)^[20] using different electrochemical techniques, such as potentiodynamic polarization, electrochemical impedance spectroscopy, and weight loss methods. The observed inhibition efficiency increased with the increase of the concentration of inhibitor with values from 27% up to 94% but decreased with increasing temperature. A higher effectiveness was obtained for ionic liquids with longer chain substituents. Table 1 summarizes the ionic liquids used in electrochemical studies and their main characteristics as corrosion inhibitors.

All ionic liquids studied acted as mixed-type inhibitors, affecting cathodic and anodic reactions through forming an adsorption film on aluminum surface according to Langmuir isotherm with physical mechanism. Based on the ΔG and ΔH values, the adsorption process is spontaneous and exothermic. This is the same behavior observed for similar alkylimidazolium ionic liquids in different substrates such as steel^[21] or copper.^[22] Although no spectroscopic experiments were performed, authors proposed the following general mechanism for the dissolution of aluminum in acid medium:^[23]

Table 1 Ionic liquids used as corrosion inhibitors using electrochemical techniques in aqueous solution

Ionic liquids	Substrate	Media	Inhibitor concentration (M)	Type of inhibition	Type of isotherm	Inhibition efficiency values (%)	Ref.
1-Butyl-3-methylimidazolium chloride	Aluminum	1.0 M HCl	10 ⁻²	Mixed	Langmuir	82	[20]

Reaction (4) is the controlling step in the metal dissolution. The interaction of the adsorbed protonated imidazolium ionic liquid molecule with the aluminum surface partly displaces the water molecules originally adsorbed on the surface.

Similar results were obtained with the aluminum alloy AA6061 as the substrate in diluted sulfuric acid (0.1–1 M H₂SO₄), but using different poly(ionic liquid)s derived from imidazolium hexafluorophosphates with different alkylic chain lengths and hexafluorophosphate

as anion.^[24] Langmuir's isotherms were in agreement with the film formation on the alloy surface, while standard free energy indicated corrosion inhibition by a physisorption process.

As before, the best corrosion inhibition results were obtained for longer alkylic chain-substituted imidazolium, but only 61% of inhibition efficiency was reached against uniform corrosion, due to the competition between sulfate species and inhibitor molecules to occupy the metallic surface area. The corrosion inhibition was confirmed using immersion tests for 30 days, but pitting corrosion still happens, although in a lower extension. Based on electrochemical, SEM, and energy dispersive X-ray (EDX) results, corrosion and inhibition mechanisms are suggested as shown in Fig. 2.

In the anodic zones of alloy AA6061 in the absence of ionic liquid, a protective oxide film is formed on the surface, which can be destroyed under the action of the diluted sulfuric acid by the interaction of the hydrated film of

**Fig. 2** Proposed mechanism of corrosion and inhibition of aluminum alloy AA6061 without/with poly(ionic liquid) in diluted sulfuric acid^[24]

aluminum oxide with bisulfate anions. As this complex is soluble in the aqueous environment, it is then desorbed from the surface, leaving free active sites to be attacked again by bisulfate or sulfate anions. In the presence of ionic liquid, the oxidation reactions are modified; $\text{Al}_2(\text{SO}_4)_3(\text{H}_2\text{O})_{n,\text{ads}}$ can adsorb one more bisulfate anion and then interact electrostatically with the cation of ionic liquid through the imidazole ring, while the hydrophobic part of the alkyl side chain is preferentially oriented toward the solution, forming a hydrophobic barrier. At the same time, the hexafluorophosphate anion can be adsorbed onto the aluminum alloy AA6061 surface, forming $\text{Al}\left[(\text{H}_2\text{O})_n(\text{PF}_6)_{4-}\right]$, which led to an excess of negative charge and could then electrostatically interact with the cation of the ionic liquid. In the cathodic zones, in the absence of ionic liquid, protons coming from acid dissociation when approaching the surface are reduced to release molecular hydrogen and consume the aluminum free electrons. In the presence of ionic liquid, ionic liquid cations competed with protons to occupy active sites on the cathodic zones, leading to adsorption of ionic liquid cations. As the size of the ionic liquid cation is higher than proton, it can cover a more extended area and the kinetics of cathodic reaction is slowed down.

The corrosion and electrochemical behaviors of pure aluminum in KOH–ionic liquid–water solutions with variable volume ratios of water and the ionic liquid 1-butyl-3-methyl imidazolium tetrafluoroborate have been studied.^[25] In alkaline medium, mechanism for the dissolution of aluminum is:

Large KOH concentration facilitates the removal of the dense oxide film, enhancing the electrochemical dissolution of aluminum, whereas corrosion decreases with the increase of ionic liquid in the electrolytes.

In the literature, it is possible to find more examples of low corrosion values of aluminum in contact with different ionic liquids. For example, dicyanamide-based imidazolium and pyridinium ionic liquids have been tested^[26] and although aluminum showed a great corrosion resistance in contact with the dicyanamide-based ionic liquids, it suffered severe damage when exposed to chloroaluminate ionic liquid. Deep eutectic solvents have also shown very low corrosion rates with aluminum even when they contain water and in the presence of chloride.^[27] As well imidazolium ionic liquids derived from dioctylsodium sulfosuccinate, a readily available pharmaceutical product, have shown^[28] lower corrosion levels and higher hydrolysis stabilities than conventional halide-containing imidazolium ionic liquids in aluminum alloys.

Finally, two choline-aminoacid ionic liquids^[29] have shown good anticorrosive properties on both aluminum and steel in a 6-h test at 100°C, showing a new application for bio-based ionic liquids as noncorrosive green lubricants.

IONIC LIQUIDS IN ALUMINUM ANODIZATION, PASSIVATION, AND SURFACE PROTECTION PROCESSES

Anodic oxidation of aluminum is a well-established technique for producing a stable aluminum oxide (Al_2O_3) film on a metal surface, commonly used in corrosion protection, by reaction (7):

Tateishi et al.^[30] described for the first time the anodization of Al by formation of Al_2O_3 films in different imidazolium ionic liquids. The formation of the Al_2O_3 layer varies with the type of ionic liquid, the applied voltage, and the water content (Fig. 3). Although water is a source of oxygen for the anodization of aluminum, there is an optimal quantity of water, which depends on the type of ionic liquid. The anion components of the IL and the water content are the most important factors, and it's thought that the electron avalanche model can explain the breakdown mechanism of aluminum anodization in an ionic liquid. The finding that the characteristics of oxide films can be adjusted by the selection of the ionic liquid and the water content suggests the potential of

Fig. 3 Anodization mechanism of aluminum in the presence of ionic liquid. The figure shows the mechanism in the case that an anion is taken into an oxide film (An: anion and Ca: cation)^[31]

ionic liquids as novel electrolytes for the anodization of aluminum.

A homogeneous Al_2O_3 film was obtained in 1-butyl-3-methylimidazolium benzoate.^[31] The water content strongly affects the characteristics of the Al_2O_3 layer, because the source of oxygen for anodic oxidation is the small amount of water (<1 wt%) present in the ionic liquids. The ionic liquid anion had an important effect on its ability to form a passive layer and on the composition of the layer. Using a constant potential of 40 V, a homogeneous barrier-type Al_2O_3 film with better properties was obtained in 1-butyl-3-methylimidazolium benzoate than film generated in 1-butyl-3-methylimidazolium mandelate, whereas a heterogeneous porous film containing a large amount of anion molecules was formed in the acetate derivative.

Using 1-butyl-3-methylimidazolium tetrafluoroborate ionic liquid as an additive^[32] in an 0.03 M oxalic acid aqueous solution in a 1:1 molar ratio concentration and using $200 \text{ mA}\cdot\text{cm}^{-2}$, a growth rate of $1.1 \text{ }\mu\text{m}/\text{min}$ was obtained using a single-step process. This value is comparable to that normally obtained in the industrially hard anodization conditions and three-fold increase of the growth rate, as compared to the bare acidic solution with the same acid concentration. Ionic liquid selection is an important point in this case because no adherent Al_2O_3 film was generated using 1-butyl-3-methylimidazolium methoxyethoxyethylsulfate, an ionic liquid with higher oxygen content and quite high conductivity, factors that theoretically should help in Al_2O_3 generation.^[33]

For the ethyl-methylimidazolium cation, the two anions bis(trifluoromethylsulfonyl)imide and bis(perfluoroethylsulfonyl)imide display similar passivation on aluminum in solvent-free ionic liquids, but the second one gives rise to a higher resistance to oxidative corrosion.^[34]

The stability of electrochemically generated aluminum oxide film in the ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate in the presence of borax and sodium dihydrogen phosphate and water in ethylene glycol has been studied by electrochemical impedance spectroscopy,^[35] showing that the oxide layer is more stable in ethylene glycol-ionic liquid solutions than in ethylene glycol-water solutions. In the case of ethylene glycol-ionic liquid solutions with only 10% ionic liquid v/v shown high conductivity, higher polarization resistance, uniform capacitance, and lower passive current.

The anodic polarization of aluminum was also studied in 1-butyl-3-methylimidazolium and *N*-methyl-*N*-butylpiperidinium tetrafluoroborate,^[36] showing the formation of a passive film composed of AlF_3 and Al_2O_3 after the first breakdown potential, while the fluoride film increased under continual anodic polarization.

The anodization of aluminum in a low-melting mixed halide molten salt, at large positive overpotentials, has been shown^[37] to be a mass transport-limited process governed by the dissolution of a passive layer

of AlCl_3 on the electrode surface. A Walden plot constructed from this data fell on the ideal line, indicating that the $\text{LiAlBr}_4\text{-NaAlCl}_4\text{-KAlCl}_4$ molten salt exhibits the expected high ionicity. The anodization of aluminum in $\text{LiAlBr}_4\text{-NaAlCl}_4\text{-KAlCl}_4$ molten salt proceeds under mixed kinetic and mass-transport control at small anodic potentials. At more positive potentials, the anodization reaction transitions to a mass-transport-limited process controlled by the dissolution of a passive layer on the aluminum electrode.^[38]

In a similar way, applying electric potential but using aluminum alloy AA5083 immersed in trihexyl(tetradecyl) phosphonium bis(trifluoromethylsulfonyl)amide,^[39] electrochemical etching could be performed. In this case, it is necessary to use a two-step anodic pre-treatment, first applying a constant current step of $2 \text{ mA}\cdot\text{cm}^{-2}$ until the potential reached 6 V and, after that, holding the potential to that value. Mg was de-alloyed from the Mg_2Si intermetallic particles, and metal ions from metal dissolution as Mg^{2+} and Al^{3+} form metal fluoride deposits with bis-(trifluoromethanesulfonyl)imide on the remaining anodic sites. Oxide layer formed on the surface decreased anodic corrosion kinetics, lowering corrosion rate in NaCl aqueous solution and increasing pitting potential. Table 2 summarizes the characteristics of different Al_2O_3 films obtained by applying potential in the presence of different ionic liquids.

The direct use of high-ordered porous templates of anodic aluminum oxide for formation of nanostructures via electrochemical deposition is hindered by the presence of the barrier alumina layer in the bottom of the pores. Zn can be deposited on a barrier alumina layer of up to 60 nm thick from a solution of ZnCl_2 in a choline chloride/ethylene glycol eutectic mixture.^[40]

In a similar way, multi-walled carbon nanotubes have been arranged in nanochannels of an anodic aluminum oxide template by a two-step anodizing process. The stabilized multi-walled carbon nanotubes in the water-soluble 1-methyl-3-octadecylimidazolium bromide ionic liquid were deposited inside the pores of the aluminum oxide template, which were made conductive by deposition of nickel nanoparticles in the bottom on the pores.^[41]

Recently, modification of abrasion resistance of anodized AA7075 aluminum alloy was observed after an electrochemical treatment in aqueous solutions of phosphonate imidazolium ionic liquid.^[42] After anodization, ionic liquid anions were introduced in aluminum oxide layer using chronoamperometry at different potentials. Electrochemical impedance spectroscopy indicated that charge transfer resistance diminishes after treatment but scratch tests under progressive load showed (Fig. 4) increased abrasion resistance with respect to the anodized alloy (79%), only when the applied voltages lay within the corresponding passivation regions. Applied voltages below or above those regions reduce the abrasion resistance of the coatings.

APPLICATIONS OF IONIC LIQUID ELECTROLYTES IN ENERGY STORAGE DEVICES

Aluminum is considered a suitable material for the cathodic current collector in lithium-ion batteries, but it may corrode in contact with the electrolytes used in that kind of devices, normally composed of 1 M LiPF_6 dissolved in ethylene carbonate mixed with different linear carbonates as dimethylcarbonate, ethylcarbonate, or diethylcarbonate. As the size of lithium-ion batteries increases for larger energy storage applications, the substitution of volatile carbon electrolytes is considered an urgent need. Room-temperature ionic liquids, with their negligible volatility, non-flammability, high conductivity, and wide electrochemical window, could be suitable candidates.

The use of ionic liquid-containing electrolytes has been shown to suppress corrosion of aluminum current collectors in lithium batteries. Many different ionic liquids have been tested in such applications trying to reduce corrosion rate.^[43] Using different derived imidazolium ionic liquids with tetrafluoroborate as anion^[44] after anodic polarization of up to 2 V vs. Ag/AgCl reference electrode, a passive film was firmly formed on the surface of Al in pure 1-butyl-3-methylimidazolium tetrafluoroborate compared to those obtained in 1-ethyl-3-methylimidazolium tetrafluoroborate and 1-propyl-3-methylimidazolium tetrafluoroborate.

When lithium bis-(trifluoromethanesulfonyl)imide salt is added to the different ionic liquids tested, only in the case of 1-butyl-3-methylimidazolium tetrafluoroborate, a passive film was obtained on Al and was stable up to a potential of 94 V. EDX and X-ray photoelectron spectroscopy characterization indicate that the passive film could be composed of Al-bis-(trifluoromethanesulfonyl)imide species on the outside and of Al_2O_3 and AlF_3 in the inside as decomposition products of Al-bis-(trifluoromethanesulfonyl)imide. Aluminum dissolution in nonaqueous solutions containing bis(perfluoroalkylsulfonyl)imides was studied in detail using electrochemical impedance spectroscopy.^[45] Changing the anion of the ionic liquid to bis-(trifluoromethanesulfonyl)imide,^[46–48] similar results were obtained after anodic polarization of up to 5.5 V vs. Li^+/Li . 1-Butyl-3-methylimidazolium bis-(trifluoromethanesulfonyl)imide was the most effective ionic liquid to inhibit Al corrosion.

In a similar way, the aluminum corrosion/passivation process in *N*-butyl-*N*-methylpyrrolidinium bis(trifluoromethanesulfonyl)imide ionic liquid has been compared to that in *N*-butyl-*N*-methylpyrrolidinium bis(fluorosulfonyl)imide. While aluminum slowly corrodes in the former, it is passivated in the latter. Aluminum electrodes have also shown to be stable in the bis(fluorosulfonyl)imide ionic liquid in the presence of chloride content <1 ppm.^[49] Aluminum current collectors have shown excellent corrosion

stability under anodic polarization in the same ionic liquid. Aluminum electrodes showed no signs of corrosion after being subjected to 10 slow voltammetric cycles of up to 5 V vs. Li/Li^+ .^[50] Ionic liquids derived from different (fluorosulfonyl)imide anions^[51–53] have been widely studied as well.

Besides tetrafluoroborate and (fluorosulfonyl)imide derivatives, electrolytes containing difluoro(oxalate)borate ionic liquids have been studied.^[54] The exceptional oxidative stability of these ionic liquids together with their noncorrosive behavior toward aluminum when mixed with lithium salts makes them suitable candidates for battery electrolyte applications.

Although most ionic liquids studied are aprotic imidazolium derivatives, some protic ionic liquids such as *N*-butyl-pyrrolidinium bis(trifluoromethanesulfonyl)imide have also been tested as electrolytes in lithium-ion batteries,^[55] finding that the amount of protic ionic liquid present in the electrolyte determines its ability to suppress the anodic dissolution of aluminum.

The major limitation of ionic liquids in this application is the relatively low power of the devices due to their high viscosity especially at room temperature. Trying to avoid this problem, mixtures of different ionic liquids and traditional solvents have been prepared. The use of 1-butyl-3-methylimidazolium tetrafluoroborate as an additive of ethylene glycol at 10% v/v^[56] as electrolyte in Al capacitors provided a high conductivity, higher polarization resistance, uniform capacitance, and lower passive current than traditional aqueous electrolytes.

In order to increase the power of the devices, a ternary mixture of a pyridinium bis-(trifluoromethanesulfonyl)imide ionic liquid, propylene carbonate, and lithium bis-(trifluoromethanesulfonyl)imide^[57,58] has been tested. In this case, the maximum potential that can be applied before the occurrence of faradic reactions at the Al surface is increased from 3.8 to 5.4 V vs Li^+/Li if only ionic liquid was used, indicating that the ionic liquid is able to suppress Al corrosion. This corrosion reduction might be related to the reduced solubility of $\text{Al}[\text{bis}(\text{trifluoromethanesulfonyl})\text{imide}]_3$ in the ionic liquid and to the formation of $\text{Al}[(\text{trifluoromethanesulfonyl})\text{imide}]_3$ species in Al surface. The studied mixture can be used both at room temperature and at 60°C. Ionic liquids based on the bis-(fluorosulfonyl)imide anion have lower viscosities due to the smaller size of the anion and thus higher conductivities than bis(trifluoromethanesulfonyl)imide-based ionic liquids but lower corrosion protection ability^[49] in the same type of mixture, especially at 60°C, observing strong pitting corrosion in SEM images. A similar cycling stability for butylmethylpyridinium bis(fluorosulfonyl)imide could be obtained if the chloride content of the ionic liquid was lower than 1 ppm. An ionic liquid based on the asymmetric (fluorosulfonyl)(trifluoromethanesulfonyl)imide anion^[50] was tested, showing quite good corrosion protection behavior. Only mild pitting took place after 140 h of

constant voltage at 3.2 to 3.5 V vs Li/Li⁺. Another strategy to overcome the problem of high viscosity of ionic liquids is the use of double-salt electrolytes containing a second salt with a BF₄⁻ or PF₆⁻ anion.^[59]

With the same objective, Kamath et al.^[60] have proposed the formation of low-stability ion-solvent complexes in ionic liquids, which facilitate the rapid aluminum-ion solvation–desolvation process, giving rise to more favorable transport properties (viscosity and ionic conductivity).

Not only ionic liquids have been tested for lithium-ion batteries; room temperature ionic liquids have also been recently described as corrosion-preventing electrolytes in aluminum-air batteries.^[61,62]

Sun et al.^[62] have described a new aluminum-ion battery with an ionic liquid electrolyte (Fig. 5) and an extremely high average voltage plateau. Conventional Li-ion and Na-ion batteries can only transfer one charge in one redox couple (Li⁺/Li or Na⁺/Na), while Al-ion batteries can transfer three charges in one redox couple (Al³⁺/Al), which can achieve more gravimetric capacity and volumetric capacity than Li-ion and Na-ion batteries.

In this type of battery, the electrode reactions for both anode and cathode could be described as follows, in the charge process:

Whereas, in the discharge process,

Fig. 5 Scheme of the aluminum-based battery^[62]

CONCLUSION

The recent advances in the development of water-stable room temperature ionic liquids with a wide range of compositions, combining different anions and cations have opened the route to new technologies and process, which will allow the control of surface coatings, electrochemical processes, and new applications of aluminum and its alloys. Although the bases have been already settled, new developments and the implementation of practical applications are expected to take place in the near future.

Abstract

In this paper, the Fe-rich phases in and their detrimental effect on aluminum alloys are summarized. The existence of brittle platelet β -Fe-rich phases lowers the mechanical properties of aluminum alloys. The methods to neutralize the detrimental effect of iron are discussed. The use of high cooling rate, solution heat treatment, and addition of elements such as Mn, Cr, Be, Co, Mo, Ni, V, W, Cu, Sr, or the rare earth elements Y, Nd, La, and Ce are reported to modify the platelet Fe-rich phases in aluminum alloys. The mechanism of the modification is briefly described. Technologies to remove iron from aluminum are reviewed extensively. The precipitation and removal of Fe-rich phases (sludge) are discussed. The dense phases can be removed by methods such as gravitational separation, electromagnetic (EM) separation, and centrifuge. Other methods include electrolysis, electro-slag refining, fractional solidification, and fluxing refining. The expensive three-layer cell electrolysis process is the most successful technique to remove iron from aluminum so far.

Keywords: Alloys; Aluminum; Iron removal; Modification.

INTRODUCTION

One of the greatest challenges to aluminum recycling is the widely varying composition of scraps. Most scraps are mixture of alloys with a wide range of compositions. Table 1^[48] shows the representative composition of pre-sorted wrought and cast alloy scraps. Particularly, iron is a serious challenge because of its gradual accumulation during repeated scrap recycling.^[51] Also, the difficulty (and therefore, cost) to remove it from the aluminum alloy increases with decreasing Fe content.^[28] Most aluminum alloy production requires tight composition controls on iron. For example, iron content level above 0.15 wt% is unacceptable in premium aerospace alloys such as 7050, 7055, and 7475, and high performance automotive alloys, like 5474 and 6111, also restrict both iron and silicon to 0.40 wt% as maximum. Thus, secondary aluminum alloys are not sources for producing premium quality aerospace alloys.^[141] The recycling and refining of scraps must reduce the impurities, especially iron, to an acceptable level. Iron is the most pervasive impurity element in aluminum alloys, which stems from the bauxite and steel tools used

during both primary and secondary production. Iron usually forms second phases in the aluminum alloys owing to its low equilibrium solid solubility in the aluminum (max. 0.05%), such as Al_3Fe , $\alpha\text{-AlFeSi}$, and $\beta\text{-AlFeSi}$.^[61] These Fe-rich phases have an appreciable deleterious effect on the mechanical properties of the alloy. The ductility and tensile strength progressively decreases with the increasing Fe content. Particularly, the ductility decreases dramatically after a critical Fe content is surpassed. The techniques applied to lessen the deleterious effect of iron have been the subjects of extensive researches for decades. The largest efforts have been made on the suppression of the detrimental impact of the iron phases, for example, structural modification by adding some chemical reagents, such as Mn, Co, and Cr.^[43,85,130,164,167] However, these metals have only a partial effect because they increase the total amount of the Fe-rich phases, which is also detrimental to Al alloys. Other elements like Be, Sr, and Ni have an influence on Fe-rich phases too but they are far less effective than Mn. There are no effective practical methods to directly remove iron from aluminum alloys by conventional refining. The techniques or theories on direct iron

removal from aluminum have made no satisfactory progress so far. Thus, the study on effective removal of iron from aluminum is urgent. Nevertheless, iron is present in most traditional die casting alloys as an impurity, yet a very useful impurity.^[3,93] A minimum of 0.8% Fe is beneficial to the high pressure die casting alloys, such as (e.g., 380, A380, C380, A383, A384, 360, A360, etc.) to prevent die sticking (i.e., soldering of the alloy to the die), improve die casting surface finish and improved resistance to hot tearing during solidification.^[157] However, concerning Fe improving the resistance to hot tearing of the alloy there are conflicting reports.^[3] The Al-Fe-Si ternary eutectic composition occurs at about 0.8% Fe. Apaljan reported that, theoretically, when iron is alloyed to a little above that amount, the supersaturated molten alloy has little tendency to dissolve the relatively unprotected tool steel while the molten alloy and die are in intimate contact.^[3]

However, in high-integrity die casting variations such as high-vacuum, squeeze, and semi solid casting iron is not tolerated at high concentrations due to the formation of β -Al₃FeSi that destroys ductility (a major goal in those alloys) by providing numerous stress raisers and points of crack initiation.^[3]

In this paper, the following topics are reviewed

- Iron-containing intermetallic phases in aluminum alloys.
- The detrimental effect of iron on the mechanical properties of aluminum alloys.
- Methods to modify Fe-rich phases.
- Methods to remove iron from aluminum alloys.

FE-RICH PHASES IN ALUMINUM AND ALUMINUM-SILICON ALLOYS

Since the solid solubility of iron in aluminum is less than 0.05% at equilibrium, almost all iron forms second phases in aluminum.^[97] The binary Al-Fe and ternary Al-Fe-Si phases are the main Fe-rich phases in aluminum alloys.^[61] Hence, the scope of this discussion is mainly about the Al-Fe-Si system.

A number of Fe-rich phases in Al-Fe-Si ternary system have been identified as shown in Table 2. Al₁₃Fe

(also reported as θ -Al₁₃Fe or θ -Al₁₃Fe₄),^[97,142] a common equilibrium phase, forms a eutectic with aluminum at about 655°C.^[61] The metastable Al₆Fe also forms a eutectic with aluminum,^[171] and its eutectic temperature is a few degree lower than that of the Al-Al₃Fe eutectic.^[6,59] The transition between Al-Al₃Fe and Al-Al₆Fe eutectic reaction is common. Moreover, the typical micro-structure, precipitated morphologies and Fe content of Al₆Fe and Al₃Fe are very similar.^[171] Thus, it is difficult to identify between the Al₆Fe and Al₃Fe. Metastable phases Al_mFe [$m \approx 4.0 \sim 4.4$],^[2] Al₆Fe, and Al_xFe [$x \approx 4.5$ or 5]^[2] usually form at a high cooling rate.^[68,94,97,171] Al_mFe is reported to be stable at the cooling rate above 10, 18, or 20°C/s; Al₆Fe is stable at the cooling rate in the ranges 1–10°C/s, 3–18°C/s, and 2–20°C/s; Al_xFe is stable at 0.5–6°C/s.^[61] However, Al_mFe, Al₆Fe, and Al_xFe were also observed at a slow cooling rate 0.16°C/s in low Fe/Si Al alloy (0.35 wt% Si, 0.23 wt% Fe). While Al₃Fe, supposed to be stable at the cooling rate below ~1°C/s,^[80] was not found; Khalifa stated that higher content of Si (Fe/Si < 1) stabilized Al_mFe, Al₆Fe, and Al_xFe and destabilized the Al₃Fe at slow cooling rates as shown in Fig. 1.^[61] Al_pFe [$p \approx 4.5$]^[2] was observed by Liu in the Al alloy containing 0.511 wt% Fe and 0.127 wt% Si at a high cooling rate 10°C/s.^[80]

q₁-AlFeSi was observed in alloys containing 0.23 wt% Fe + 0.49 wt% Si or 1.03 wt% Fe + 0.62 wt% Si alloy at a high cooling rate of 14°C/s as shown in Fig. 2.^[61] Liu found q₁-AlFeSi in the alloy with ~0.25 wt% Fe, ~0.125 wt% Si at the cooling rate 10°C/s and q₂-AlFeSi was observed after further heat treatment at 600°C for 24 h, as shown in Fig. 3.^[80] γ -Al₈FeSi was reported to usually exist in the high silicon and high iron Al alloy.^[97] Plate-shaped δ -Al₄FeSi₂ was reported in earlier references.^[97,119] Mondolfo reported that δ -Al₄FeSi₂ formed in high Si content Al alloys.^[97] However, Khalifa observed the δ -Al₄FeSi₂ phases in low Si alloys at a cooling rate >10°C/s in alloys with Fe content ranging from 0.23 to 0.56 wt% and Si content ranging from 0.35 to 0.9 wt%, as shown in Fig. 4.^[61] δ -Al₄FeSi₂ was also described as δ -Al₃FeSi₂.^[71]

The most important Fe-rich phases in aluminum alloys containing silicon are β -phase and α -phase. The α -phase is identified most commonly as α -Al₈Fe₂Si, α -Al₁₂Fe₃Si₂,^[97] α -Al₁₅Fe₃Si₂^[28] or generally α -AlFeSi.^[61,80,142] There is a

Table 2 Identified Fe-rich phases in aluminum alloys

Fe-rich intermetallics	Crystal structure	Reference
Al_mFe	Bct	[61,80]
Al_6Fe	Orthorhombic C-centered	[61,97] [80]
Al_xFe		[61,171]
$Al\rho Fe$	Bcc	[80]
$\theta-Al_3Fe$ or $\theta-Al_{13}Fe_4$	Monoclinic C-centered monoclinic	[61,97,127] (Liu et al. 1986)
$\alpha-Al_8Fe_2Si$ or $\alpha-Al_{12}Fe_3Si_2$	Hexagonal	[28,61,97,127,142]
$\alpha-Al_{15}Fe_3Si_2$ [28]	Bcc	[25,70,140]
$\beta-Al_3FeSi$	Monoclinic	[28,61,97,127,142]
$Al_9Fe_2Si_2$ [118]	B-face centered orthorhombic Orthorhombic Tetragonal	[17] (Zheng et al. 2000) [70]
$\delta-Al_4FeSi_2$ [71,113]	Tetragonal	[28,61,71,97]
$q_1-AlFeSi$	orthorhombic	[61,80]
$q_2-AlFeSi$	monoclinic	(Liu et al. 1986)
$\gamma-Al_8FeSi$	monoclinic	[97,142]

contradiction about the structure of the α -phase.^[140] Proved the α -phase was body-centered cubic and^[25] described it as $Al_{19}Fe_4MnSi_2$, with space group Im3, and $a = 1.256$ nm. Kral substantially proved it as $Al_{19}(FeMn)_5Si_2$, space group Im3, $a = 1.256$ nm.^[69,70] While in other references, the structure of the α -phase was reported as hexagonal.^[28,97,142] The α -phase has a compact morphology such as Chinese script, star like

and polygon [shown in Fig. 5^[82] and Fig. 6],^[35] which was thought to be much less harmful than the platelet $\beta-Al_5FeSi$ to the mechanical properties of Al alloys. Dinnis found the α -phase exhibited two distinct morphologies: coupled Al- α -AlFeSi eutectic with convoluted arm structure and polyhedral crystal as seen from Fig. 6^[35] when it precipitates as primary phase.^[35] The platelet β -phase

Fig. 2 Morphology of q_1 -AlFeSi phase in the aluminum alloy with 0.23 wt% Fe + 0.49 wt% Si or 1.03 wt% Fe + 0.62 wt% Si at 14°C/s^[61]

Fig. 3 TEM morphology of q_2 -AlFeSi phase in an aluminum alloy^[80]

Fig. 4 Morphology of δ -Al₄FeSi₂ phase in an aluminum alloy^[61]

Fig. 5 Typical morphology of α -phase and β -phase in aluminum^[82]

is usually identified as β -Al₃FeSi,^[15,28,97] Al₉Fe₂Si₂^[118] or generally β -AlFeSi.^[61,142,146] There is also conflicting conclusion regarding the structure of β -phase. Monoclinic was accepted by many researchers.^[28,97,103] Murali stated that β -Al₃FeSi is monoclinic with $a = 0.5792$ nm, $b = 1.2273$ nm, $c = 4.313$ nm, and $\beta = 98.93$ deg.^[103]

However, Carpenter claimed that β -phase was B-face centered orthorhombic with $a = 0.6184$ nm, $b = 0.6250$ nm, and $c = 2.069$ nm;^[17] Zheng observed that the β -phase was orthorhombic with $a = 0.618$ nm, $b = 0.620$ nm, and $c = 2.08$ nm.^[180] Kral claimed the β -phase was consistent with tetragonal Al₃(Fe, Mn)Si₂ with space group I4/mcm, $a = 0.607$ nm and $c = 0.950$ nm.^[70] However,^[69] claimed that the structure of β -phase was consistent with that of the δ -phase in his further study.

Among all the Fe-rich phases, β -AlFeSi is thought to be the most deleterious, and most efforts have been devoted on how to avoid the formation of β -AlFeSi. β -AlFeSi has an undesirable platelet morphology as shown in Fig. 5^[82] and Fig. 7,^[35] which is brittle and generally assumed to act as stress raisers and points of weak coherence. Usually, higher iron content and slow cooling rate result in the increasing size of β platelets.^[146] The domination of platelet β -phases results in serious loss of strength and ductility in Al-Si cast alloys. It is notable that α - and β -phase may not clearly exhibit the dendrite or platelet shape respectively and are difficult to be identified by their morphology, especially when the alloys are eutectic modified by Na or Sr.^[70]

Fig. 6 Three-dimensional reconstruction of α -phase: (a) original two-dimensional photo; (b) three-dimensional α -phase with high convoluted arms observed^[35]

Fig. 7 Three-dimensional reconstruction of β -phase, (a) original two-dimensional phases; (b) three-dimensional β -phase^[35]

EFFECT OF IRON ON THE MECHANICAL PROPERTIES OF ALUMINUM ALLOYS

In some alloys, iron is added intentionally. For example, iron is commonly added to Al-Cu-Ni alloys to improve the high-temperature strength. For Al – low Mg (<2 wt%) alloys iron is used to reduce germination. For Al-Fe-Ni alloys, iron is added to reduce the corrosion in steam at elevated temperature. In the aluminum conductor

materials, iron is added to improve strength without substantial conductivity loss.^[97] Specifications normally permit considerably more Fe to be present in permanent mould and pressure die-cast alloys compared to sand-cast alloys because the cooling rate is higher in these cast conditions, thus, the size of the constituents is finer. Particularly, in the commercial process of pressure die casting, the Fe content is above 0.8wt%, and the precipitated eutectic Al-Si-Fe composition prevents the molten alloys from sticking

(called “soldering” to the die that causes a deterioration in the mould) and hence improves the surface quality of the component.^[143] In these cases, Fe is an alloying element.

The mechanical properties of cast aluminum alloy are generally imperiled by the presence of iron.^[27] Three-dimensional morphological results of Fe-rich intermetallic compounds observed by co-authors of this paper in their paper on inclusions in aluminum, Fig. 8,^[30] suggests that Fe-rich intermetallic phases have much more complex morphologies, with fragile and brittle appearance than what is shown in two-dimensional observation. These morphologies could explain why they are detrimental to the mechanical properties of aluminum.

Al-Cu

The presence of Fe is generally reported to have a detrimental effect on the ductility, strength, and fatigue properties of aluminum alloys. But a few investigations reported a slight improvement in strength and ductility with the increasing of Fe content as shown Table 3. In Al-Cu alloys, needle-like Cu_2FeAl_7 phases precipitate,^[27] which are brittle and act as stress raisers like β -Fe phases, reduce the strength and ductility of the alloy. The formation of Cu containing Fe-phases also reduces the effective Cu content of the alloy. Since it is impossible to dissolve this compound even with the subsequent solution heat treatment, the amount of Cu available for hardening is considerably reduced.

Al-Mg

The influence of Fe on the Al-Mg alloy is shown in Table 4. Usually, increasing of Fe content reduces the elongation (ductility) and tensile strength. However, it was^[27] observed that the elongation and tensile strength improved with iron content increased to 0.6 wt% in Al-10Mg-0.5Si alloy. In Al-3wt% Mg or 6wt% Mg alloys, an increase

in iron content from 0.2 to 0.8 wt% resulted in a slight improvement in tensile strength.^[27] An increase in the tensile strength with iron content, result was also obtained by Bonsack^[27] in Al-Mg-Zn alloy and Chadwick and others^[18] in Al-0.7 Mg-1Si wrought alloy.

Al-Zn

The ductility of Al-Zn alloys decreases with increasing iron content in aluminum alloys due to the formation of needle like FeAl_3 phase.^[27] Iron was also added as anti-recrystallizer to Al-Zn-Mg-Cu alloys.^[44] Kholnova^[62] found 0.2–0.4 wt% addition of iron ensured satisfactory ductility and fracture toughness. With Fe content <0.1 wt%, the alloy had poor casting properties and a coarse grained structure, low impact toughness and corrosion resistance; when Fe content ≥ 0.4 wt%, the fracture toughness is again impaired. Some data are shown in Table 5.

Since the Al-Si alloys are the most common and important, there are many studies on the effect of Fe. The literature has been thoroughly reviewed by Couture.^[27] A basic consistent conclusion was that Fe has a small effect on the properties up to a certain level, and when the iron content exceeds that critical level the properties drop rapidly. When the Fe level exceeds about 0.7 wt%,^[97] the $\beta\text{-Al}_5\text{FeSi}$ usually forms at roughly the location of the eutectic trough on the Al-Fe-Si phase diagram (Fig. 9).^[61,97] The apparent critical Fe level is related to the formation of primary $\beta\text{-Al}_5\text{FeSi}$, which is brittle and detrimental. Cooling rate and certain alloying elements can increase the critical Fe content.

Although the negative effects of iron are clear, the mechanisms involved are not fully understood.^[91] Originally proposed the “restricted feeding” theory, suggesting that $\beta\text{-Al}_5\text{FeSi}$ increases porosity by blocking feeding channels since the platelet $\beta\text{-Al}_5\text{FeSi}$ forms in the interdendritic channels during solidification.^[122] Claimed that the β platelets were active sites for pore nucleation and growth,

also influenced the ultimate shape of pores—called “pore nucleation theory”. While^[149,150,151] reported their results conflicted with the former two theories for Al-5Si-1Cu-0.5Mg alloys, and they substantially proved that the porosity was due to the effect that the platelets have on the nucleation and growth of eutectic silicon.^[14,15] Thought that the porosity was due to the presence of double-over oxide bi-films, which were common in the aluminum melt. Its wetted side is the favored substrates for the nucleation and growth of β -Fe platelets. After solidification, the interface between the two sides of an entrained oxide film becomes the crack, as shown in Fig. 10.^[14] As an aside^[95] also found the nucleation and growth of Sr-rich compounds on the wetted side of double-over oxide bi-films, which may give another explanation for the increasing tendency of microporosity formation by Sr modification in Al-Si alloy.

Fig. 10 Growth of b-Fe phase (the white rod) on the entrained oxide film (the black line in the white rod)^[14]

MODIFICATION OF PLATELET IRON PHASES WITH ADDITION OF OTHER METALS

Mbuya et al. discussed that the addition of a suitable neutralizer like Mn, Cr, Be, Co, Mo, Ni, V, W, Cu, Sr, or the rare earth elements Y, Nd, La, and Ce could sever to control the deleterious effect of Fe in aluminum alloys.^[93] Platelet Fe-rich phase is mainly the brittle β -Al₅FeSi phase in Al-Si cast alloy. In Al-Cu alloys, Cu₂FeAl₇ also has a kind of long needles shaped morphology, which tends to embrittle the alloy,^[97] as mentioned earlier. Modification/neutralization of the Fe-rich phases can be obtained by modifying the platelet morphology and promoting the compact morphology such as Chinese script, polyhedral or star like shape. Some earlier studies^[27] and recent studies, which mainly focused on Al-Si-Mg cast alloys,^[102,104,105,106,107,108,109,158,166,167,178] showed the modification of needle-like phases. However, the iron content usually maintains the same level after the treatment. The total proportion of Fe-rich phases increases with Fe content (plus Mn and Cr) and gradually imperils the properties of alloys even after the modification/neutralization treatment.^[27]

Manganese (Mn)

Although Mn by itself is also harmful to the mechanical properties of aluminum alloys, it is widely used to neutralize Fe in Al-Si cast alloys. Manganese has low cost and is readily available. Mn has an atomic radius and crystal structure close to Fe as seen in Table 6.^[85] Literature on the neutralization of platelet Fe-rich phases by Mn addition is abundant. Couture has written a detailed review on this topic.^[27]

Mondolfo claimed that with the addition of sufficient manganese the platelet Fe-rich phases transformed from the brittle platelet to the compact morphology such as Chinese script, globule or polyhedral with a resulting restoration of the tensile strength and elongation.^[97] $\beta\text{-Al}_5\text{FeSi}$ tends to be suppressed and $\alpha\text{-Al}_{15}(\text{Fe}, \text{Mn})_3\text{Si}_2$ is formed after the Mn addition.^[97] In the ternary, Al-Si-Mn alloy, $\alpha\text{-Al}_{15}\text{Mn}_3\text{Si}_2$ forms. In quaternary Al-Si-Fe-Mn alloys, iron may replace up to 90 pct of manganese in this phase to form $\alpha\text{-Al}_{15}(\text{Fe}, \text{Mn})_3\text{Si}_2$.^[36] The morphology of $\alpha\text{-Al}_{15}(\text{Fe}, \text{Mn})_3\text{Si}_2$ changes with the cooling rate and the concentration of Si and Mn.^[28,50,53,63,110] The crystal structure of $\alpha\text{-Al}_{15}(\text{Fe}, \text{Mn})_3\text{Si}_2$ in wrought alloy is reported to be $\alpha\text{-AlMnSi}$, simple cubic (sc) with a $\text{Pm}\bar{3}$ space group^[26] or $\alpha\text{-AlFeSi}$, body-centered cubic (bcc) with a disordered $\text{Im}\bar{3}$ space group.^[25] Yoo reported that the crystal structure of precipitated $\alpha\text{-Al}_{15}(\text{FeMn})_3\text{Si}_2$ depended on the Mn/Fe ratio.^[168] Kim found the rod-type $\alpha\text{-Al}_{15}(\text{FeMn})_3\text{Si}_2$ had a bcc ($\alpha\text{-AlFeSi}$)/sc ($\alpha\text{-AlMnSi}$) dual structure or just $\text{Pm}\bar{3}$ structure in skeleton-type as shown in Fig. 11.^[63] It was reported that the increase of Mn in $\alpha\text{-Al}_{15}(\text{FeMn})_3\text{Si}_2$ changed its crystal structure from disordered $\text{Im}\bar{3}$ to ordered $\text{Pm}\bar{3}$.^[25,37] Kim claimed the critical Mn/Fe value for disorder-order transition of $\alpha\text{-Al}_{15}(\text{FeMn})_3\text{Si}_2$ lay within the range of 0.11–0.66.^[63] Murali observed that β -platelets transformed into very coarse polyhedral with the presence of 1.3 wt% Fe and 0.53 wt% Mn in the sand cast in Al-7Si-0.3Mg alloy, while more Chinese scripts were found at lower Fe content 0.87 wt% and 0.35 wt% Mn at a high cooling rate (chill castings).^[105] Ashtari studied the effect of Mn and Sr additions on $\beta\text{-Al}_5\text{FeSi}$ modification in Al-6.5Si-3.5Cu-1.0Fe alloy. With the 0.015wt%

addition of Sr in the Mn free alloy, only the refinement of eutectic Si and $\beta\text{-Al}_5\text{FeSi}$ was observed. With the combined addition of 0.015wt% Sr and 0.3wt% Mn, both $\alpha\text{-AlFeSi}$ and $\beta\text{-Al}_5\text{FeSi}$ was observed. No evidence was stated that Sr improved the transformation of $\beta\text{-Al}_5\text{FeSi}$.^[4]

According to Shabestari,^[127] high Fe content in aluminum encourages the formation of star like $\alpha\text{-AlFeSi}$ in Al-12.7Si alloys as shown in Fig. 12. A linear relationship between segregation factor ["SF"]^[5,29,49] and the amount of intermetallic compounds at short holding time was obtained. Figure 13^[127] shows the relationship and the function can be described as $\text{Volume (\%)} = 1.33\text{SF} - 1.53$,^[127] and the cooling rate was stated as 10°C/s. In Al-7.0 Si-0.38 Mg (A356)

Fig. 12 Effect of Mn and Fe on the formation of intermetallic compounds in Al-12.7 Si-0.1 Cr alloys^[127]

Fig. 13 Volume fraction of intermetallics versus the segregation factor (SF)^[127]

alloy, with the addition of Mn from 0.07 to 0.20 wt%, the platelet β -Fe were replaced by globular or Chinese scripts α -AlFeSi as shown in Fig. 11.^[63] Zhang observed that the platelet β -Al₅FeSi was converted to α -AlFeSi with the condition of Mn/Fe = 1.28, Fe = 1.09 wt% in Al-12 Si-0.3 Mg alloy, the cooling rate was not stated in the report.^[172]

The amount of manganese needed to neutralize iron is still not well established^[27,28] because the neutralization process is deeply affected by many factors, such as cooling rate, heat treatment, initial Si and Fe content, and other elements. Generally, it is desirable to have a weight percentage Mn/Fe ratio of 1:2 if the Fe content exceeds 0.45 wt%.^[23] Mascré arrived at a different neutralization formula for sand and permanent mold castings: Mn% = 2 (Fe% - 0.5).^[91] However, Cao found the Chinese script α -AlFeSi even with the Mn/Fe = 0.17 in an Al-11.6 Si-0.37 Mg-1.16 Fe alloy as shown in Fig. 14.^[14] Mn modified Fe-rich compounds have a greater tendency to

Fig. 14 SEM image of Al-11.6 Si-0.37 Mg-1.16 Fe-0.29 Mn showing typical Chinese script of α -Fe^[14]

segregate and to form coarse primary α -Fe, which imperils the tensile strength and ductility of Al alloys.^[27,28]

In Al-Cu alloys, Mn addition encourages the formation of Chinese script phases and suppresses the platelet Cu_2FeAl_7 .^[97] Tseng reported that Mn addition recovered the ductility but caused a further loss in the yield strength of Al-Cu alloys. The primary constituents were needle shaped Cu_2FeAl_7 at low content of Mn (0.29 wt%). Upon the further addition of Mn (0.66 wt%), almost all the Cu_2FeAl_7 transformed into the Chinese script Mn-bearing particles either in low Fe alloy or in high Fe alloy as shown in Fig. 15.^[152] However, the structure or stoichiometry of the Mn-bearing particles was not mentioned. In Al-Mg alloys, Mn transformed Al_3Fe into (Fe, Mn)Al₆ and improved the corrosion resistance of the alloy.^[97]

Fig. 15 CuAl_2 , Cu_2FeAl_7 , and Mn-bearing compounds in aluminum alloys, (a) 4.64Cu-0.05Fe-0.29 Mn; (b) 4.67Cu-0.05Fe-0.66 Mn; (c) 4.58Cu-0.31Fe-0.29 Mn; (d) 4.52Cu-0.30Fe-0.67 Mn; (arrow1: CuAl_2 ; arrow2: Cu_2FeAl_7 ; arrow3: Mn-bearing)^[152]

Cobalt

Fe, Cr, and Co have similar atomic radii and Cr also has the same Bravais lattice with Fe as shown in Table 6. Thus, Cr and Co can also be used to precipitate Fe-rich phases. There are few investigations on the effect of Co and Cr on the modification of Fe-rich phases. Co was thought less effective than Mn and a higher amount of addition was needed. Co/Fe ~ 0.5–1.0 was suggested as an appropriate addition to modify the platelet Fe phases to globular shape.^[27] Mahta et al.^[85] reported that the optimum ratio of Co/Fe was ~1.0 for A413 Al-11Si alloys and the Co-Fe phases were identified approximately as $\text{Al}_{15}(\text{Fe}, \text{Co})_4\text{Si}_2$, while^[105] stated the Co-Fe phase was $\text{Al}_{14}\text{Co}_2(\text{Fe}, \text{Si})$. It was reported that almost all the transformed Chinese script α -AlFeSi phases precipitated within α -Al dendrites (Fig. 16),^[27,28,85,105] which reduced the segregate tendency. Thus, Co is much less harmful than Mn. However, the presence of Co (< 1 wt%) at low concentration was reported to encourage the formation of primary Si as well as the α -AlFeSi phases in Al-11Si alloys as shown in Fig. 16b.^[85] This work has not been referred by earlier references.^[27,28,105]

Fig. 16 Microstructure of Co transformed platelet Fe phases, (a) 11Si, 2.4Fe, 2.4Co; (b) 0.6Fe, 0.3Co^[85]

Chromium

Mondolfo^[97] claimed that Cr was a possible additive to neutralize Fe phases in aluminum. Cr was believed more effective than Co, and a ratio of Cr/Fe = 0.33 can prevent the formation of β -AlFeSi.^[85] The function of Cr is similar to that of Co. Mahta reported that the identified transformed Chinese script α -Fe phase was close to $\text{Al}_{15}(\text{Fe}, \text{Cr})_3\text{Si}_2$, agreeing with Crepeau's report^[28] while different from Murali's report [$\text{Al}_{25}(\text{Fe}, \text{Cr})_3\text{Si}_4$].^[105] As with Co, a low amount of Cr also resulted in the formation of primary Si in Al-11Si alloys, as shown in Fig. 17.^[85] Different from Co, the transformed α -phases by Cr were observed both in α -Al dendrites and the interdendritic region,^[85,105] which was the same as during Mn modification [Fig. 17(a)^[85]].

Beryllium

Murali considered beryllium was a more effective neutralization element than Mn, Co, and Cr.^[107] Crepeau reported that the addition of Be > 0.4 wt% was required,^[28] while other references showed that the trace addition of Be 0.06–0.27 wt% was enough.^[104,107,158,166] Beryllium along with Fe, Al, and Si can form Chinese script or polygon Be-Fe phases identified as $\text{Al}_8\text{Fe}_2\text{BeSi}$ while other literatures described as $\text{Al}_4\text{Fe}_2\text{Be}_5$.^[28] It is notable that Be-Fe

Fig. 17 Microstructure of Cr transformed platelet Fe phases, (a) 11 Si, 0.56 Fe, 0.23 Cr; (b) 11Si, 2.68 Fe, 0.83 Cr^[85]

Fig. 18 Be-Fe phases in Al-7Si-0.3 Mg alloys, (a) Be 0.23 wt% Fe 0.21 wt%; (b) Be 0.26 wt% Fe 0.82 wt%^[158]

phases precipitated inside of the primary α -Al dendrites (like Co)^[104,105,106,107,109,158] as shown in Fig. 18,^[158] which favors fracture toughness, whereas the β -AlFeSi phase is in the inter-dendritic region.^[158] observed that the addition of beryllium to Al-Si-Mg alloys hindered the crack propagation on Be-Fe phases. Particularly, small amount of Be addition results in the formation of stable Chinese script α -Al₈(Fe, Mn)₂BeSi in 5XXX series alloys. The modification decreases the platelet iron phases formation during annealing and improves the mechanical properties as shown in Fig. 19.^[125] However,^[166] did not report the Be-Fe phases with an addition of 0.11 wt% Be in Al-11Si alloys, but the platelet phases were transformed to α -AlFeSi.

The addition of beryllium changes the solidification sequence of Fe-rich phases. The ternary eutectic reaction to generate β -AlFeSi is substituted by a peritectic reaction

Fig. 19 Microstructure of 5xxx alloys (0.42Si-0.46Fe-0.044 Cu-0.291 Mn-3.47 Mg-0.003Cr) containing 0.009 wt% Be^[125]

Table 7 Mechanical properties of stirred cast and extruded Al-7Si-0.3 Mg alloys^[104]

0.96 Fe + 0.26 Be	11.3 ± 0.5	8.0 ± 1

that forms Be-Fe phases, which replaces the β -AlFeSi phases in Al-Si-Mg cast alloys.^[107,158] In the stirred cast and extruded Al-7Si-0.3 Mg alloys,^[104] the beryllium addition lowered the detrimental effect of Fe-rich phases on the ductility and impact energy in sand cast alloys by a small amount as shown in Table 7, and it was explained that the stirring eliminated the peritectic reaction, and Be-Fe phases was found in the interdendritic region as well as in the primary α -Al.

Table 8 shows the effect of Be addition on mechanical properties of the sand cast Al-Si-Mg alloys. The deleterious effect of Fe has been neutralized such that the strength and elongation remained more or less unaffected as Fe content increased from 0.1 to 0.94wt%. Figure 20^[158] shows the mechanical property changes in Al-7Si-0.3Mg-0.2Ti alloys with the Fe content,^[158] indicating that the UTS (Ultimate Tensile Strength) of beryllium-added alloys decreases little with the increasing iron content. Moreover, the addition of beryllium led to grain refinement in the Al-Si-Mg

Table 8 Mechanical properties of sand-cast Al-Si-Mg alloys with trace Be addition^[107]

Fig. 20 Mechanical property of aluminium alloys changes with the content of Fe and Be^[158]

alloys.^[33] Thus, the refinement effect of beryllium also contributed to the mechanical properties improvement.^[107,158]

Strontium

Strontium has been used to modify the eutectic silicon phases from acicular to lamellar in Al-Si cast alloys.^[20,21,54,131] In aluminum wrought alloys, Sr was also applied to transform the platelet Fe-rich phases to α -AlFeSi ($\text{Al}_8\text{Fe}_2\text{Si}$).^[22,99,100,101] In 6063 alloys (0.2–0.6 Si, 0.45–0.9 Mg), the 0.01–0.5 wt% addition of Sr promoted the formation of α -AlFeSi and improved the extrusion characteristics significantly.^[99] It was reported that the 0.01–0.10 wt% addition of Sr to Al-Cu-Mg-Zn wrought alloys refined the inter-metallic phases.^[159] Tensile strength and conducting property were improved by approximately 0.1 wt% Sr addition into 6201 alloys (0.45–0.65 Si, 0.50–0.65 Mg).^[22] Figure 21 shows the comparison of UTS and YS with or without Sr addition in 6201 alloys.^[22] The Sr-treated alloys exhibit ~5% higher UTS and YS than that of the Sr-free alloys at high magnesium content (0.6 wt%). Mulazimoglu observed that 0.015 wt% Sr addition was

enough to modify the platelet phases in 6063 and 6201 alloys.^[100] The modification of β -AlFeSi was achieved at 0.013 wt% Sr addition in synthetic 6061 alloys (0.7 Si, 0.5 Fe, 0.88 Mg, 0.11 Mn) with the cooling rate 2°C/s, while in commercial 6061 alloys (0.7 Si, 0.3 Fe, 0.9 Mg, 0.02 Mn) the Sr addition must be increased to 0.031 wt%.^[101] A slower cooling rate favored the modification of β -AlFeSi with Sr addition in 6061 alloys.^[101] In 1XXX series alloys (0.3–1.0 Si, 0.3–1.0 Fe), where Fe and Si are the major impurities, Sr addition effectively promoted the formation of α -AlFeSi, as shown in Fig. 22.^[101] A higher cooling rate ($>2^\circ\text{C/s}$), ~0.06 wt% addition of Sr, and Si/Fe ratio <1 resulted in almost 100% of α -AlFeSi formation.^[101] The mechanism of the modification may be associated with the adsorption of Sr as a surface active element. It is presumed that Sr can be absorbed on the surface of primary α - $\text{Al}_8\text{Fe}_2\text{Si}$ phase to act as a barrier for the dissolution. Thus, the peritectic reaction $\text{L} + \text{Al}_8\text{Fe}_2\text{Si} \rightarrow \text{Al} + \text{Al}_5\text{FeSi}$ will be hindered.

Sr was also reported to modify β -AlFeSi phases in Al-Si cast alloys.^[27,129] Lu and Tang claimed that the addition of Sr suppressed the formation of β platelets.^[82,146] Shabestari reported that (0.04–0.06 wt%) Sr addition not only transformed β -AlFeSi to Chinese script α -phase but also reduced the size of platelet β -AlFeSi by fragmentation in Al-12Si (413) alloys.^[129] Yie and Pucella proved the fragmentation of platelet β -AlFeSi and marginal reduction of platelet by Sr addition in Al-11Si alloys.^[121,166] Ashtari indicated that the size and amount of platelet β -AlFeSi were reduced after Sr addition but no transformation of platelet β -AlFeSi in Al-Si-Cu-Fe alloy.^[4] Samuel observed that only primary β -AlFeSi dissolved in the α -Al matrix by peritectic reactions at 0.03–0.06 wt% Sr addition in Al-6 Si-3.5 Cu (A319) alloys.^[124] However, many studies showed that there was no transformation or reduction of platelet β -AlFeSi phase after Sr addition.^[4,124,143,166] Suarez-pena' and Lu also showed that no obvious transformation occurred except that the β -AlFeSi phase became thinner after the 0.04 wt% Sr addition in Al-12Si alloy.^[82,143] Cho reported that the combined addition

Fig. 21 Mechanical properties of synthetic 6201 wires (aging at 160°C for 5 h), (a) Tensile strength; (b) Yield strength^[22]

Fig. 22 Effect of Sr on 1XXX series alloys. (a) No Sr; (b) 0.06 wt% Sr^[101]

of phosphorus and strontium could suppress the formation of β -AlFeSi phases by the pre-existing of $\text{Al}_2\text{Si}_2\text{Sr}$ phases, which was caused by deactivation of AIP nuclei, in Al-10Si alloys.^[19] The fragmentation mechanism of β -AlFeSi is related to nucleation and growth: The addition of Sr causes a high supersaturation of the element Fe and Si, thus, the primary β -AlFeSi phase precipitates before the primary α -Al in the liquid. Then, the primary α -Al dendrites nucleate onto the primary β -AlFeSi phase and reject Fe into the residual liquid. The secondary needle-like β -AlFeSi phase nucleates due to a generalized undercooling induced by Sr.^[19,22] The growth rate of the secondary phase is much lower than that of the primary phase, thus, the smaller β -AlFeSi phases precipitate.^[143] It was also reported that the added Sr was absorbed on the nucleation sites of the β -AlFeSi phase (called poison), thus, the amount of the β -AlFeSi phase was reduced.^[19,117,129]

Molybdenum (Mo), Nickel (Ni), and Sulfur (S)

Molybdenum, Nickel, and Sulfur are much less used to modify iron phases in aluminum alloys. However, Mo was claimed to convert platelet iron phases to compact, star-shaped compounds,^[134] and to be much more effective than Mn.^[27] A combined addition of Mo (0.05–0.3 wt%) and S (0.01–0.2 wt%) was reported to improve the

mechanical properties of Al-6 to 12 Si alloys.^[27] Ni was mentioned as a “neutralizer” in some references.^[27,28,97]

MODIFICATION OF PLATELET IRON PHASES WITH THERMAL INTERACTIONS

Molten Aluminum Superheating

Mondolfo reported that the size of Fe intermetallic compounds decreased as the superheating temperature increased up to 500°C above the melting point.^[97] Crepeau claimed that Chinese script α -phases formed instead of platelet β phases when the melt temperature was >800°C, the subsequent thermal cycling of the melt slightly affected the Chinese script morphology.^[28] The conclusion was confirmed by other references.^[5] Narayanan claimed that α -phases formed at the temperature around 200–300°C above the liquidus temperature for Al-6Si-3Cu alloys due to the domination of α alumina inclusions at the superheating temperature in the melt, which was a poor nucleus for β phase. While γ alumina inclusions, acting as a nucleus for crystallization of β phase and forming at low melt temperature $\leq 750^\circ\text{C}$, transformed to alumina inclusions at the superheating temperature.^[110] However, the high superheating temperature in aluminum alloys is not recommended owing to the increasing of gas pick-up, oxidation loss and the formation of oxide inclusions as well as higher energy costs and furnace wearing.

Cooling Rate

According to the Al-Fe-Si phase diagram [Fig. 9^[61,97]], the β -Fe rich phase is a stable phase under the equilibrium cooling rate. When casting is conducted under a very high cooling rate and/or the melt is superheated to a high temperature, however, the iron rich phase crystallizes into the α -phase in metastable forms.^[55,110] The cooling rate increases as the critical content level of Fe to form β -Fe increases. For example, 0.75wt% Fe -1°C/s , 0.9wt% Fe -5°C/s , and 1.0wt% Fe -10°C/s .^[91] Passmore et al. reported that the Cu_2FeAl_7 phase was fine and evenly distributed in the chilled Al-Cu alloy while in the slowly cooled metal the Cu_2FeAl_7 phase was coarse and concentrated at the interdendritic region, which was detrimental to the mechanical properties.^[115] Narayanan reported that with increasing cooling rate and melt superheating temperature, the precipitation temperature of the β -Fe phase decreased until the β -Fe rich phase merged with the silicon eutectic temperature. The chemical composition of the remaining liquid favored the crystallization of the α -Fe rich phase in Al-6Si-3Cu alloys.^[110] The refinement and fragmentation of the β -Fe phase also can be obtained by a high cooling rate. Sigworth reported that the rapid solidification not only reduced the dendrite arm spacing but also refined the β -AlFeSi phase.^[138]

Heat Treatment

Fe-rich phases can be dissolved, fragmented and globularized during the solution heat treatment at the solidus temperature.^[28] High treatment temperature is required because of the low diffusivity of Fe in the solid aluminum. Barresi et al. (1993) reported that the π -Al₈FeMg₃Si₆ phase was transformed to the β -Al₅FeSi phase by the solution heat treatment. After the treatment, the β -Al₅FeSi phase became the predominant phase. The reduction of the π -Al₈FeMg₃Si₆ phase implied that Mg went into solid solution, which was favorable for the age hardening to improve the strength of the cast alloy (Barresi et al. 1993). But this method is limited by the possible damage caused by incipient melting.^[28]

IRON REMOVAL TECHNOLOGIES

Precipitation of High Fe-Rich Phases

The method is mainly applied to purify Al-Si cast alloys. Iron is removed by the formation of primary Fe-rich intermetallics, generally, primary α -Al₁₅(Fe, Mn)₃Si₂ or α -Al₁₅(Fe, Mn, Cr)₃Si₂ (called “sludge”). The crystallization of the sludge under an appropriate holding temperature and an initial Fe and Mn content has proved to be an effective method to remove Fe from Al-Si alloys, as shown in Fig. 23.^[43] An empirical equation is presented to simulate the kinetics of the nucleation and growth rate of the sludge. This method is a well-established technique for Al-Si cast alloys. The process consists of two steps: formation of primary Fe-rich intermetallic particles, followed by the removal of the particles. The alloy is melted and held at a high temperature (750–800°C) for some time in order to be well homogenized. Then, the melt is cooled to a holding temperature in the range of 600–650°C for the formation and growth of the sludge^[43,121] (De Moraes 2006). After

the formation of the sludge, further steps including gravity separation, filtration, electromagnetic (EM) separation or centrifuge separation are conducted to remove the sludge phase from the molten aluminum^[16,43,78,128] (De Moraes 2006). The iron concentration generally decreases from 1 to 2 wt% to at most 0.4 wt% after the treatment^[14] (De Moraes 2006).

Mn or the combination of Mn and Cr are used to form sludge^[111,128,154] (De Moraes 2006). The formation of sludge can be predicted by an iron equivalent value (IEV, referred to elsewhere as the “sludge factor”^[29] in the initial Al-Si alloy.^[49] The IEV represents an attempt to integrate the combined effects of some important impurities: Fe, Mn, and Cr. The generally accepted formula was reported as:^[5,38,49,60]

$$IEV = (\text{wt}\% \text{Fe}) + 2(\text{wt}\% \text{Mn}) + 3(\text{wt}\% \text{Cr}) \quad (1)$$

A high IEV implies the easy formation of sludge phase. Czikel et al. and Jorstad predicted the sludge formation by temperature and IEV as shown in Fig. 24.^[60,29] Jorstad discussed that the Fe:Mn:Cr ratio of 1:2:3 gives a realistic view of the sludge factor for determining the tolerable limits for a given melt. For instance, a sludge factor of 1.8 is indicated as suitable for a furnace operating temperature of 660–663°C (1220–1225°F) whereas a sludge factor of 2.2 is considered too high for a furnace temperature of 660–663°C (1220–1225°F).^[60] In Al-12.7Si alloys with a constant 0.30 wt% Mn and 0.1Cr, the temperature variation of for the formation of sludge versus iron content is shown in Fig. 25.^[127] However, some researchers treated the ratio of Mn/Fe as the most critical process parameter, and believed that it was necessary to increase Mn addition to obtain a low Fe-level.^[111] Flores^[41] claimed that with a holding temperature of 620–640°C the addition of Mn (2.2 wt%) decreased the Fe content from 1.5 to <0.3 wt% in Al-9.2 Si alloys, while with the addition of 0.6 wt% Mn decreased the Fe content from 1.2 to about 0.7 wt%. The presence

Fig. 23 Effect of holding time and initial Fe, Mn content on the formation of sludge; alloy I: 9.5 Si-0.6 Mn-0.8 Fe; alloy II: 9.5 Si-0.8 Mn-1.3 Fe; alloy III: 9.5 Si-1.5 Mn-1.5 Fe; alloy IV: 9.5 Si-2.2 Mn-1.6 Fe. (a) mass of sludge segregate isothermally at 605°C; (b) mass of sludge segregated from alloy IV at different holding time^[43]

Fig. 24 Sludge factor (SF) diagram showing the temperature and composition at which the sludge can form^[29]

of 0.2 wt% Cr accelerated the gravity segregation process without improving Fe reduction ratio. Further studies on the nucleation and growth of sludge in Al-9.5Si alloys were also conducted by Flores.^[43]

The formation of primary AlFeMnSi phases can be predicted more correctly by Al-Fe-Mn-Si phase diagrams [Figs. 26, 27].^[7] Obtained good agreement between the calculated phase diagram (using ThermoCalc) and experimental data as shown in Fig. 26 and Fig. 27. As in Fig. 26(a), the formation of primary α -Al (Fe, Mn)Si can occur at high temperature with high Mn content. With a low addition of Mn (~0.3 wt%) and ~600°C, the primary β -Al (Fe, Mn)Si phase can precipitate from the liquid. When the iron content increases, the composition range of the primary α -Al (Fe, Mn)Si phase changes, and the high temperature

Fig. 25 Temperature for sludge formation in Al-12.7Si-0.3Mn-0.1Cr-xFe alloys [the curve can be expressed by $T (^{\circ}\text{C}) = 645.7 + 34.2 \times (\text{wt}\% \text{ Fe})$]^[127]

favors this process (Fig. 26b). According to Fig. 27, the content of Si also changes the formation range of sludge.

There are some new theories about the formation and segregation of Fe-rich phases. It was reported^[12] that Fe content decreased from 0.57 to 0.47 wt% after holding for 10 min at 600°C with the presence of 0.59 wt% Mn in Al-11Si-0.4Mg eutectic alloy, and the nucleation and growth of Fe phases on the wetted side of the oxide films led to the reduction in the amount of both oxide films and Fe-rich phases remaining, which resulted in a moderate improvement in tensile properties of the alloy.

In addition to the Mn and Cr, Sr also was used to form sludge combined with Mn.^[113,121] Pucella reported that the addition of Sr at 620°C pouring temperature precipitated

Fig. 26 Calculated isopleths at 10.0 wt% Si, (a) 1.0 wt% Fe; (b) 3.0 wt% Fe (Δ : experimental data)^[7]

Fig. 27 Calculated isothermal sections at 660°C, (a) 10.0 wt% Si; (b) 14 wt% Si (Δ : experimental data)^[7]

the high Fe sludge of $\alpha\text{-Al}_{12}(\text{Fe, Mn, Cr})_7\text{Si}_2$ as well as transformed polyhedral sludge particles.^[121] Cao and Campbell reported that the mass of sludge particles with Sr addition was significantly increased at a temperature of 900°C compared with Sr-free samples, and under the same condition, the number of sludge particles was dramatically increased, which resulted in an effective Fe reduction.^[13]

Gravity Separation

Gravity separation is a method employed to remove the sludge. The melt is held at the sludge formation temperature for a relative long time. Longer settling time and lower holding temperature encourages higher iron removal efficiency.^[154] Observed that sludge formed and segregated immediately during the cooling from a high temperature (840°C) to a holding temperature of 600°C. Reported removal efficiency data were summarized in Table 9. Flores and Cao reported an Fe removal fraction over >70% with Mn/Fe > 1 and relative high Fe content.^[14,41,43] When the Mn/Fe = 1, the removal fraction of Fe decreased to ~50%.^[16,14] Figure 28a^[77] shows a microstructure of an aluminum alloy after gravity separation for a long time. Most of the sludge settled to the bottom and thus the upper part of the alloy was purified. Figure 28b^[16] illustrates the precipitated primary $\alpha\text{-Fe}$ particles. The white polygons and Chinese scripts are the sediment sludge phases.

Figure 29^[128] shows the variation of sludge volume percentage, the average size and number of particles per area at different location of the mold of Al-12Si-1.2Fe-0.29Mn-0.1Cr alloys at different holding times. Obviously, the

volume percentage, the number, and average size of sludge increase with distance from the melt surface.^[41,43,128] The removal fraction by settling varies with the position in the melt due to the depletion of the sludge near the surface and the increase near the bottom. The settling speed of sludge particles can be roughly calculated by Stokes' law. As shown in Fig. 30,^[128] the final terminal velocity can be reached at very short time, but the velocity is low.

Filtration

Primary, Fe-rich intermetallic particles can also be removed by porous filters similar to the removal of nonmetallic inclusions by filtration. Figure 31 (De Moraes 2006) shows the schematic steps of the filtration operation. After a short time (10–20 min) holding at sludge formation temperature, the melt is decanted through a preheated filter. By the way, small amount of sludge also precipitates at the bottom of the melt during the holding time. The holding time used for filtration is much shorter than holding time used for gravity separation and so filtration is suitable for the continuous treatment.^[154]

Concluded that finer-pore foam filters can remove small size sludge particles but actually only slightly increased the removal efficiency because the captured small particles easily blocked the filter pores. Data in Table 9 proved this conclusion. The efficiency of the filtration process is also affected by the initial aluminum composition. The efficiency increases with increasing Mn = Fe (>1) or initial Fe and Mn content (Table 9).^[111,153] The entire efficiency of the filtration process for the same experimental condition

is relatively low compared with other separation methods according to the studies by Nijhof et al.^[111] and Van Der Donk^[153] (Table 9). The filtration efficiency can be substantially improved by a preliminary gravity separation step.^[42] Firstly, used gravity separation to purify the aluminum melt (initial composition wt%: 1.5 Fe, 2.25 Mn, 9.2 Si, 0.2 Cr, 0.76 Zn, and 3.53 Cu) for 180 min at 640°C and

the iron content decreased from 1.5 to 0.73 wt%; then the upper part of the purified melt was filtered and Fe content was decreased to 0.27 wt%. Approximately, 82% Fe was removed overall. High efficiency was also obtained in the same way by De Moraes et al.^[32] (Table 9). A slow cooling rate from the melting temperature to the holding temperature and a longer holding time (30 min) encouraged

Fig. 30 Settling speed of the sludge as a function of time^[128]

the formation and growth of the primary iron intermetallic particles, which resulted in a high removal efficiency (De Moraes 2006).

Centrifugal Separation

The centrifugal separation technique was applied to directly remove iron-rich phases from the partially solidified aluminum alloy melts without any other elements addition, which will be discussed later. Matsubara et al.^[92] studied the sludge removal from Al-11Si alloys by the centrifugal separation technique. The centrifugal separation apparatus that was used is shown schematically in Fig. 32.^[92] The iron-rich phases moved to the edge side of the melt and the central part was purified as shown in

Fig. 33.^[92] Figure 34^[92] shows the microstructure of the inner and outer part of the melt. The rotational speed has a great influence on the purification efficiency as shown in Fig. 35.^[92] When the rotational speed is 8.3 s^{-1} , small sludge particles are unable to be expelled from the central region and the Fe and Mn content in the central region remained at a high level $>1\text{wt}\%$. As the rotational speed increases over 16.6 s^{-1} , the Fe and Mn content in the center are slightly affected by the rotation speed (Fig. 35). The ratio of Mn/Fe affects the formation and growth of primary Fe-rich phases and thus the iron removal fraction varied with Mn/Fe as seen in Fig. 36.^[92] With increasing the ratio of Mn/Fe, the iron removal fraction increases and Mn/Fe = 1.5 is the optimum value removing $\sim 86\%$ Fe. The removal fraction of Fe slightly decreases when Mn/Fe exceeded 1.5.

EM Separation

The principle of EM separation of particles from liquids was first proposed by Kolin,^[65] and by Leenov and Kolin.^[73] All of the other studies are based on their theory. They considered a single spherical particle or a cylinder having infinite length, placed in conducting liquid with imposition of DC EM field. In this field, direction of the magnetic field is perpendicular to that of the electric current, thus the direction of EM force is perpendicular to both directions. They calculated the migration force by analyzing the EM-flow around the particle. Their analysis has been further modified by some researchers. EM separation of inclusions from molten metal has been investigated since 1961.^[87,155] In the 1980's, the principle of applying

Fig. 31 Schematic of the filtration process (T1: melting temperature, T2: holding temperature) (De Moraes 2006)

Fig. 32 Schematic of vertical centrifugal separation apparatus^[92]

Fig. 33 Microstructure of the transverse cross section of the centrifugal separated melt^[92]

EM forces to inclusion separation was further investigated by Refs. [90,98,116]. Patel and El-Kaddah^[116] analyzed migration force to a single particle in magnetic field having various angles with respect to the current direction. EM separation of inclusions from molten aluminum is an emerging and promising method for the production of ultraclean aluminum alloys to meet the growing demand for clean aluminum alloys.^[40,86,112,114,116,144] Using numerical technique,^[134,135] recently analyzed the single particle with wall proximity effect, and they also studied the problem of the two particles with their direction in a row parallel to EM force.

Figure 37 shows the principle of EM separation. When a uniform EM force is applied to a liquid metal, the metal is compressed by the EM force (Lorentz force) and a pressure gradient is generated in the metal. The non- or less-conductive particle suspended in the liquid metal receives only the pressure force because it does not experience the EM body force. As a result, the particle is forced to move in the opposite direction of EM force. Based on the Leenov-Kolin's theory,^[65,73] a non- or less-conductive spherical particle receives a force in a conductive fluid with the imposition of a uniform EM force. This force is expressed by

$$F_p = -\frac{3}{4} \frac{\pi d_p^3}{6} F \quad (2)$$

Inner part

Outer part

Fig. 34 Typical microstructure of inner and outer parts by centrifugal separation (Al-11Si-2Fe-3Mn)^[92]

Fig. 35 Effects of rotational speed on the concentration distribution of Fe and Mn in Al-11Si-2Fe-3Mn^[92]

Fig. 36 Removal fraction of Fe versus Mn/Fe ratio^[92]

where F_p is the force acting on a particle, d_p particle diameter, F imposed EM force, which can be expressed by

$$F_p = J \times B \quad (3)$$

where J is the imposed electric current density (A/m²), and B is the imposed magnetic flux density (T).

As this force acts inversely against the EM force, it can be applied for the separation of non- or less-conductive particles from the liquid metal.

Several researchers have proposed the application of EM force to inclusion separation. The methods of the imposition of the EM force are classified into the following types:

- simultaneous imposition of direct current and stationary magnetic field^[90,114,169,170]
- imposition of Alternating Current (AC)^[147]
- imposition of alternating magnetic field^[40,74,136,163]
- imposition of traveling magnetic field^[145]
- simultaneous imposition of alternating current and alternating magnetic field^[1,148]
- imposition of stationary magnetic field^[120] and
- more recently, strong magnetic field created by a superconducting DC coil^[88] were also presented

Compared with other methods, AC magnetic field (type c) shows great advantages because no loop circle is needed for the imposed current and no metal electrode is needed, which usually contaminates the melt.^[137]

Korovin^[66,67] deduced the theory of separating non-metallic inclusions in the melt by using alternating magnetic field induced in an infinitely long solenoid. El-Kaddah^[39] designed an AC magnetic field for the separation of inclusions from melt, by which the adjustments of the direction of imposing magnetic field become easier. He calculated the particle motion in the molten pool of the EM separation process and found that a vigorously stirred melt may cause problems with the separation of small inclusions due to the entrapment of the inclusion particles within flow eddy.

Fig. 37 Principle of electromagnetic separation of inclusions from the molten metal

Also, due to the weak magnetic field in most areas opposite to the coil, the removal efficiency is badly influenced.^[40] The flexibility of applying the AC magnetic field generated in an induction coil to the particle separation was theoretically demonstrated by Yamao et al.^[163] They also found that the higher removal efficiency was obtained for a circular crucible in a strong magnetic field, where complete mixing is assumed to account for the effects of melt flow on the inclusion separation efficiency. Shu et al.^[137] studied the EM force exerted on the particles in a cylindrical melt and the relation between various processing parameters and the removal efficiency theoretically.

The advantages of EM separation include:

- Efficient, even for $< 50 \mu\text{m}$ small inclusions: The main advantage of EM separation is that the EM expulsive force exerted on inclusions is only dependent on the difference in electrical conductivity between the inclusions and melt, and independent of the density, chemical composition, or different phases (solid, liquid, or gas) of the inclusions.^[73,90] Thus, for the purification of molten aluminum, EM separation can, in principle, remove even micrometer-sized inclusions at an almost constant rate by using high-intensity EM force fields.^[40,116,137]
- Environmentally clean (no salt input): Another advantage is that it offers very clean processes in view of environmental protection, because the use of fluxes, generally chlorides or fluorides, is avoided, that is, no salt input. With growing concerns about the role of materials in sustainable development,^[47,126,162] materials processing industries are paying more attention to the environmental friendliness of the processing methods

while pursuing material performance. EM separation really satisfies this point.

- No contamination to the metal: The melt is also protected against contamination if induction technology is utilized, since there is no contact between the melt and the power source due to the intrinsic properties of the magnetic fields,^[47] and there is no extra lining refractory introduced.
- Easy adjustment: Unlike conventional separation techniques, the magnitude and direction of the separation force on the particle can be easily modified by controlling the direction and intensity of the electric and magnetic fields in the liquid.

Since the conductivity of Fe-rich phases is less than that of molten aluminum, they can be separated by EM forces. The mechanism is shown in Fig. 37.^[77] Some Chinese and South Korean researchers^[57,58,64,77,78,79,160,161,165,173,174] have applied EM separation method to remove iron (in the form of sludge) from the melt. Particularly, the compact morphology of sludge is favorable for the uniform direction of repulsive force. It is necessary for the successful removal of sludge.^[77] Li et al.^[78] observed that the iron content decreased from 1.13wt% to 0.41 wt% after the treatment in Al-12Si-1.1Fe-1.2Mn alloys, the micro-structure before and after the process is shown in Fig. 38.^[77] However, the platelet β -Fe was unable to be separated because its needle-like morphology resulted in the disorder repulsive force and the platelets moved in random direction [shown in Fig. 38(b)].^[78] Li et al.^[78] theoretically proved that the removal efficiency increased with increasing EM forces and the diameter of sludge particles, and decreased with increasing the velocity of flowing melt and the height of separator. Equation 4 gives the definition of removal efficiency.^[78] Here, it is simply assumed that $u_f = 0.5u_M$ and u_M is the maximum velocity of the melt. The gravity influence was neglected because the EM force is much larger than that of the gravitational force. It was reported that the removal efficiency of $\geq 20\mu\text{m}$ sludge particles was 100% with $8.7 \times 10^5 \text{ N/m}^3$ EM force, $u_f = 121.3 \text{ mm/s}$ and 5 mm separator height.^[77,78]

$$\eta = \frac{3zBJ}{8huf} \times \frac{d_p^2}{24\mu} \quad (4)$$

where η is the removal efficiency; z is the melt flow direction (Fig. 37); B is the magnetic flux density vector; J is the current density; h is the height of the separator; u_f is the average velocity of the melt; d_p is the diameter of sludge particles; and μ is the viscosity of the melt.

Xu et al.^[161] also proposed the removal efficiency of EM separation as follows:

$$\eta = \frac{3xv_t}{4hu_M} \quad (5)$$

Fig. 38 Electromagnetic separation of Al-12Si-1.1Fe-1.2Mn alloys, (a) Before EM separation; (b) After EM separation^[77]

$$v_t = \frac{d_p^2}{18\mu} \left[(\rho_p - \rho)g + \frac{3}{4}BJ \right] \quad (6)$$

where η is the removal efficiency; x is the melt flow direction; v_t is the terminal velocity of particles; B is the magnetic flux density vector; J is the current density; h is the height of the separator; u_M is the maximum velocity of the melt; d_p is the diameter of sludge particles; μ is the viscosity of the melt; ρ_p is the density of sludge particles; ρ is the density of melt; g is the acceleration due to gravity. Xu's model included the effect of gravity. If the gravity influence is neglected, Eq. 6 is simplified into Eq. 7. Substituting v_t in Eq. 5 by Eq. 7 and with $u_f = 0.5u_M$, Eq. 4 will be obtained.

$$v_t = \frac{3d_p^2BJ}{72\mu} \quad (7)$$

Actually, Xu also observed that the gravity influence was rather weak. Figure 39^[161] shows the removal efficiency under different technological parameters. Figure

Fig. 39 Relationship between removal efficiency and technological parameter: (a) u_M , maximum velocity of the melt; (b) f , EM force ($f = |B \times J|$); (c) x , action length of f ; (d) $2h$, height of separation chamber (Xu et al. 2003)

39a illustrates that the removal efficiency drops quickly with increasing u_M . Figure 39b shows that the removal efficiency of $\geq 30 \mu\text{m}$ particles is over 90% when the EM force was $1.5 \times 10^5 \text{ N/m}^3$. Figure 39c shows that $>30 \mu\text{m}$ particles can all be removed if $x = 120 \text{ mm}$. The best iron removal fraction was approximately 65.8% in Xu's study.^[161] Jiao reported an iron removal fraction of 70%.^[58] Kim and Yoon^[64] successfully purified Fe from 1.64 to 0.45 wt% in Al-7Si scraps. The iron decreases with increasing of electric current as shown in Fig. 40,^[64] which confirms the removal efficiency theory of Li. Figure 41^[64] shows the Al-7Si scrap microstructure processed by the EM separation for 60 s with a magnetic field of 0.3 Tesla. With 10–30 A induced currents, the angular sludge settled on the side and bottom of the tube, but accumulated at the bottom of the tube at 40 A. Therefore, a higher current favors iron removal. However, the main factor controlling the removal efficiency of iron was initial Fe and Mn content as well as the size of sludge.^[77]

Table 9 shows reported iron removal efficiency by different sludge separation methods. Comparing with gravity and filtration, EM separation appears more efficient under similar experimental conditions. Furthermore, EM separation can also remove nonmetallic inclusions, which

Fig. 40 Removal efficiency of Li from aluminum by EM separation with different currents^[64]

has been proven by many researchers.^[76,133,134,135] EM separation is suitable for large industrial scale of continuous treatment, and has already been used for aluminum refining by several Chinese aluminum companies. Gravitational separation can achieve a high iron removal but needs long settling time. Gravitational settling is nonfeasible for

Fig. 41 Distribution of sludge with induction (a) 10, (b) 20, (c) 30, and (d) 40 A^[64]

large scale treatment because the sediment sludge causes serious built-up and the low holding temperature is inappropriate for industrial operation, and it is a batch process. The combination of gravitational separation and filtration gives impressive iron removal results but the disadvantages during gravitational separation step are still there, in addition to the problem of clogging of filter pores. Although the centrifuge has relatively high removal efficiency, it is also unpractical for the large scale processing due to challenges with temperature control, rapid increasing of contracted solid phases, the need for centrifuge cleaning, and the need for further processing of the compact solid residues.^[139]

Electrolysis

The expensive process of three-layer-cell electrolysis is the most successful technique for the removal of iron and silicon from the molten aluminum so far.^[154] Figure 42 shows

Fig. 42 Sketch of three layers electrolysis process

a sketch of a three-layer refining cell. The impure molten aluminum anode (9), the barium-sodium-aluminum halide electrolyte (7) and the pure molten aluminum (5) form three layers in the cell. Only aluminum in the anode can be dissolved through the reaction $Al - 3e^- = Al^{3+}$ during the electrolysis process and Al^{3+} deposits on the cathode—the carbon electrode at the top of the cell (6). Because the pure molten aluminum is the lightest, it will stay on the top of the three layers. Thus, the purified aluminum is obtained. However, the energy consumption for this process is relatively high, $\sim 13\text{--}14 \text{ kWh kg}^{-1}$ so far.^[9,81,89,179] This technique is also applied to purify commercial aluminum with low level of initial impurities into high purity.^[156]

Fractional Solidification

The technique is based on the distributions coefficient (k) of impurities. For k less than unity, a much lower contents of impurities will result in the solidified than that in the residual liquid.^[83,84] The distributions coefficient of iron is 0.03 therefore; it can be removed from aluminum by this method. However, the technique is not suitable for normal aluminum foundries owing to their low productivity, thus economically unfavorable. Large scale fractional solidification is used to produce extreme purity aluminum (99.999 wt% Al)^[31,175,176,177] and the aluminum used for fractional solidification is also required to have a relatively high purity (99.993 wt%). It is reported that iron content decreased from 747 to 24 ppm after 2 h processing in a fractional solidification apparatus.^[56] Zhang et al.^[176] developed a new fractional solidification apparatus as shown in Fig. 43. High purity grade of Al

Fig. 43 Sketch of the fractional solidification apparatus developed by Zhang^[175]

(99.993 wt%) and extremely low Fe content 0.6–0.9 ppm was achieved.^[176]

Electroslag Refining

Electroslag refining process (ESR) is a secondary refining process in which the slag or flux is used both as a heating source and as a refining medium, as shown in Fig. 44.^[10] The process is already well established for ferrous metals but has not been used for aluminum refining. Early attempts^[11,123,132] indicated that no iron removal was observed, except that Mohanty's investigation^[96] reported 26% iron removal (from 0.22 to 0.16 wt%) from commercial aluminum by ESR with a flux containing aluminum phosphide. Further investigations on the use of ESR in aluminum refining have not been reported.

Fluxing Refining

Few references have reported that significant iron removal can be achieved by using flux. The studies of the current author showed that the addition of $\text{Na}_2\text{B}_4\text{O}_7$ flux with NaCl and KCl significantly lowered the iron content from 0.33 to 0.18 wt%^[46] in laboratory experiments. The possible mechanism was the formation of stable Fe_2B phases by the reaction between iron and the $\text{Na}_2\text{B}_4\text{O}_7$ and the simultaneous capturing process by the flux. However, industrial scale experiments showed little removal of iron. Nijhof et al.^[111] reported iron removal with a mixed flux of NaCl, KCl, and NaF as shown Fig. 45, an iron removal from ~0.9 to ~0.7 wt% was obtained. However, the mechanism and detailed processing were not mentioned in his paper and no further studies were reported.

Direct Centrifugal Separation of Fe-Rich Phases

During the method of centrifugal separation, the melt is cooled to a temperature at which solid phases form, that is, the melt is partially solidified. The first solidified phases include mainly silicon, iron, or titanium. Then, the centrifuge is started and cooling is continued. Liquid is expelled from the solid framework and collected. Temperature is an important factor controlling the removal efficiency of impurities because the precipitation of solid crystals contributes to the success of extraction. Singleton and Robinson^[139] reported that near-eutectic phase was obtained after the successful centrifugal separation of raw aluminum alloys (30 wt% Si, 4 wt% Fe, 2wt% Ti) in a centrifuge bowl apparatus (Fig. 46). The separated solidified phases, which were primary silicon and $\delta\text{-AlFeSi}$, are shown in Fig. 47.^[139] The formation of network structure was due to the different density of precipitated phases. This rigid and porous structure was desirable for the flow of liquid without blocking, which was an important requirement to use centrifugal separation technology in real practice. The composition of filtrate from the centrifuge varied with the separation temperature, as shown in Fig. 48.^[139] Iron content decreased from 4 to ~1wt% after the centrifuge was at ~600°C. A higher separation temperature imperiled the separation efficiency of impurities.^[52] Carried out a centrifugal separation experiment for an aluminum alloy of composition (12.52wt% Si, 1.87 wt% Fe, 0.94 wt% Ti) and reported a removal of over 50% iron and 90% Ti at 580°C separation temperature, while no iron removal at > 650°C as shown in Table 10. The extracted impurity containing solidified phases was claimed to contain TiAl_3 and a mixture of TiAl_3 and $\beta\text{-AlFeSi}$ at 650°C and 580°C respectively.^[75] Developed a mathematical model to predict

Fig. 46 Centrifugal apparatus, (a) Components of the removable-wall centrifuge bowl; (b) The centrifuge bowl assembled^[139]

Fig. 47 Extracted solidified phases by centrifugal process: left, predominantly silicon; right, silicon plus d-AlFeSi^[139]

Fig. 48 Relationship between filtrate composition and separation temperature^[139]

the migration velocity of the solid phase at every moment during the solidification process of Al-Fe alloys under centrifugal casting. Brun et al.^[72] studied the relationship between the collected mass of particles and the centrifugal time for Al-2.5Fe-1.5Mn alloys by water model, laboratory scale and pilot scale experiments, however, no iron removal efficiency was stated in his paper.

Table 10 Composition of Fe, Si, and Ti in aluminum after centrifugal separation^[52]

Impurities	Initial	650°C	580°C
Si (wt%)	12.52	12.4	11.66
Fe (wt%)	1.87	1.9	0.81
Ti (wt%)	0.94	0.38	0.09

The energy used in the process of direct centrifugal separation is much lower than the electrolysis process. In addition to the separation of primary Fe-rich phases, the centrifugal separation method is also applied to remove sludge in Al-Si alloys from the melt as described in section A.3 of the current paper.

SUMMARY

It is well known that iron has a detrimental effect on aluminum alloys. The formation of brittle needle-like β -Fe-rich phases, as stress raiser and points of fracture, is the main reason for the decline in the properties of the alloys. The iron removal techniques are mainly focused on the formation and separation of primary α -Al (FeMn)Si. More efforts are devoted on the modification of platelet iron rich phase in aluminum.

The detrimental effect of iron can be partially reduced by increasing cooling rate, solution heat treatment and the addition of neutralization elements. The modification process is complicated and unpredictable because it is deeply affected by casting conditions and the initial content of impurities. Mn is the most common element used for neutralization. Manganese in the alloy increases the total amount of Fe-rich phases, which is also harmful to aluminum alloys. Cr and Co have equal or more modification ability than Mn, but increase the total amount of Fe-rich phases. Be seems a good choice but it is toxic. Available data shows the neutralization effect of Sr as marginal and still needs further investigation before being applied.

So far, three-layer-cell electrolysis is the most successful technique to remove iron from the aluminum but it is expensive and only suitable for high purity aluminum production, because all the impurity elements are removed from the feed material. The precipitation of Fe-rich phases (sludge) is a well-established method for laboratory scale but difficult for continuous treatment process. The technology of EM separation can efficiently remove Fe-rich phases and could be a continuous process. EM separation is faster than gravitational separation, and avoids the problem of pore blockage during the filtration process. Due to the disadvantages of Mn addition, new elements that can efficiently form “sludge” should be investigated. The elements close to Fe in the Periodic Table may be good choices. The feasibility for the formation of Fe-rich compounds in Al-Fe-X system can be thermodynamically evaluated. Since it was reported that the electroslog technique removed 26% Fe from aluminum with the presence of aluminum phosphides, aluminum phosphide seems a clue for the removal of iron too. The flux refining is also a good way to remove iron, which is easy to be applied by industry. $\text{Na}_2\text{B}_4\text{O}_7$ flux processing is a possibility and more effort should be devoted on it.

In summary, the following further studies will be carried out:

- Exploring new elements that can efficiently neutralize iron phases in aluminum alloys or form primary Fe-rich phase at high temperature (700–750°C).
- Exploring possible flux to directly remove iron from aluminum alloys.
- Theoretical and experimental study on the removal of sludge [primary $\alpha\text{-Al}_{15}(\text{Fe}, \text{Mn})_3\text{Si}_2$] from Al-Si alloy melt through EM separation.

Abstract

Machining is one of the most important manufacturing processes. Aluminum and its alloys play a critical role in component manufacture. This article will provide the reader with a current overview of machining practices which will include: aluminum alloy classification, machining performance measures such as cutting forces, tool life, chip forming and breakability, cutting tool design, and area that provide continuing process challenges such as high-speed machining, dry machining and machining of aluminum metal matrix composites.

Keywords: Alloy classification; Aluminum metal matrix composites; Cutting tool high-speed machining; Machining performance parameters.

INTRODUCTION

Machining constitutes one of the major and most important manufacturing processes. Typically, a machining operation is one of the final requirements in the production of a component used in the industrial sector including the automotive and aerospace industries. In these industries, aluminum and its alloys continue to play a critical role in the manufacture of components. Of particular importance to designers is the high strength to weight ratios which aluminum enables and good appearance characteristics. The addition of alloying elements and subsequent tempering processes have made aluminum and its alloys into viable alternatives for traditional steels in many applications. However, with this newfound thrust towards using aluminum and aluminum alloys, considerable confusion and apprehension has been caused due to the corresponding inability to predict the machining performance when using a particular aluminum alloy.

This chapter is aimed at providing professionals involved in machining of aluminum an up-to-date perspective on the current state-of-art and the future directions in aluminum machining. Initial emphasis is placed on the classification of the aluminum alloys, since a major portion of process planning decisions are dependent on the properties of the material being machined. The chapter then focuses on the topic of machining performance, the different machining performance measures such as cutting forces, tool-life, chip-form/chip breakability, etc. and their impact when machining aluminum and its alloys. The increased challenges in machining aluminum alloys has resulted in innovative approaches towards the design

of cutting tools, especially diamond-based cutting tools. This issue is addressed with correlation to the effects on the machining performance. Finally, three current challenging areas which provide much future scope are studied, namely: (i) high speed machining of aluminum alloys; (ii) dry machining of aluminum alloys; and (iii) machining of aluminum-based metal matrix composites (MMCs).

CLASSIFICATION OF ALUMINUM AND ITS ALLOYS FROM A MACHINING STANDPOINT

A detailed classification of aluminum and its alloys based on the work material properties, temper grades, individual effects of alloying constituents, etc., has been provided in many handbooks and research literature (e.g. *ASM Specialty Handbook: Aluminum and Aluminum Alloys*.^[1]) In this section we deal with the classification only from a machining standpoint and the effect of such a classification on the selection of the tooling (from the cutting tool geometry such as inclination angles, rake angles, etc. for the corresponding cutting conditions such as feed, cutting speed and depth of cut.) A broad general classification of aluminum alloys can be made on the basis of the primary mode of fabrication of the alloy and its properties and capabilities as follows:

- Cast alloys.
- Wrought alloys.
- Strain-hardenable alloys.
- Heat-treatable alloys.

A more specific of classification of aluminum alloys can be made on the basis of the quantity of the silicon content in the material; namely, low-silicon content and free-machining aluminum alloys; and high-silicon content aluminum alloys.

Low-Silicon Content and Free-Machining Aluminum Alloys

These alloys are classified on the basis of their low silicon content which is typically less than 12%. They are also termed as hypoeutectic alloys. Typical examples of alloys falling under this classification are: 2024-T4, 6061-T6, 2011-T3, Duraluminum, etc. These materials are generally rather soft and gummy and have a tendency to stick to the cutting tool when machining. They are also characterized by low melting temperatures. Built-up edge problems may occur during machining due to the tendency to stick to the cutting tool. They can be machined by carbides as well as diamond-based tools (PCD or diamond coated tools).

High-Silicon Content Aluminum Alloys

These alloys are based on their comparatively higher silicon content which is usually greater than 12%. They are also commonly termed as hypereutectic alloys. Typical examples of such alloys are: A390, A390-1, etc. These materials are more abrasive to machine and the degree of abrasiveness increases with an increase in the silicon content. This abrasiveness is usually caused by the hard particles of free silicon which are dispersed throughout the material. The constitution of such alloys results in tearing of the material when machining rather than the usual shearing mechanism. Cutting forces are comparatively higher when compared with low-silicon content alloys. Carbide tools cannot be used for machining these alloys and the most effective cutting tool materials are the diamond-based cutting tools. These alloys are now finding wide application in the automobile industry.

MACHINING PERFORMANCE

The assessment of machining performance is a much sought-after goal of manufacturers keen on achieving excellent quality at reasonable costs. However, there have been very few attempts at a comprehensive definition for indicating the machining performance. The term “machinability” has been traditionally used to indicate some level of the machining performance, however, it has been largely restricted to the work material alone. Machinability ratings for aluminum alloys span into 5 groups, with ratings: A, B, C, D and E; and are ordered in increasing order of chip length and decreasing order of surface quality. In many cases changing the temper grade on an alloy will improve the chip breakability, thereby improving the machinability.

A case in this regard is the application of a T6 temper to the 2024 and 7075 alloys; this results in an improvement in the machinability rating from D (continuous, unbroken chips) to B (curled and easily broken chips). Table 1 shows the machinability ratings for wrought aluminum alloys whereas Table 2 shows the machinability ratings for cast aluminum.^[1] However, it must be noted that the ratings in these tables must need constant updating due to the tremendous advances in cutting tool materials, coatings and chip breaker geometries.

Machining Performance Measures

In order to shift the traditional focus of machinability on the work material to a more comprehensive level involving the technological machining performance which includes the other two major components of the machining system (namely the cutting tool and the machine tool in addition to the work material), a comprehensive consideration of important measures which indicate the machining performance needs to be taken into account. These performance measures typically include the following:

- **Cutting force/power/torque:** This provides important diagnostic information on the energy required to machine the work material, thereby indicating the level of machining performance and the ease or machinability of cutting the material. This measure also gives important interrelated insights into the other performance measures such as tool-wear and chip-form.
- **Tool-wear/tool-life:** The tool-wear and ensuing tool-life indicate the level of performance attainable for that particular work material–cutting tool–machine tool combination under a given set of cutting conditions. The progressive tool-wear significantly affects the other machining performance measures. The rate of tool-wear is a most frequently used performance measure.
- **Chip-form/chip breakability:** The chip-form and chip breakability are immediate and easily recognizable performance measures for assessing machinability. In fact, in order to quickly assess the machining performance, the chip form is an invaluable indicator of the level of machining performance. The direct reference to machinability of the work material (in this case, aluminum alloy) in general however needs to be counter-balanced by an appropriate consideration of the cutting tool (the tool material – substrate and coating; and the chip-breaker configuration).
- **Surface roughness/surface integrity:** The surface quality, as indicated by the surface roughness, and to a lesser extent, the surface integrity (in terms of direct visual observation as well as a simple test of the surface roughness) provide immediate information regarding the level of machining performance.
- **Part accuracy:** The part accuracy is one of the least modeled of machining performance measures, despite

its significance in product specification. It has very close interrelationships with the other performance measures. The accuracy achieved during the machining process provides valuable information about the performance attained and possible indicators for rectification.

Cutting Force/Power/Torque

The cutting force or power required to machine aluminum alloys is generally much lower than that for conventional steels and irons. From a productivity viewpoint, the low cutting forces generated when machining aluminum alloys are thus an advantage when selecting aluminum alloys as the work material. Figure 1 shows the effect of cutting speed on five different aluminum alloys.^[2] In a very direct reference to the machining performance, it is clear that the 2011-T3 alloy provides the best results of the surveyed materials from general machining knowledge; the lower

cutting forces exhibited in this plot confirm the good machinability of 2011-T3 alloy.

The use of flat-faced and grooved cutting tool inserts result in variation in cutting forces. Also, changes in the cutting parameters such as feed and depth of cut will cause changes in the cutting forces. One of the more complex operations involved in machining is the contour turning operation. From a research point of view, the contour turning operation provides an opportunity to study the effect of continuous variation of effective tool geometry (due to the varying side-cutting edge angles and effective rake and inclination angles) and the cutting parameters such as depth of cut on the machining performance. Figures 2(a) and 2(b) show the variation of cutting forces along the contour (in terms of effective side-cutting edge angle) for a flat-faced (PCD) tool and a grooved (CVD diamond-coated) tool respectively,^[3] when machining 2011-T3 aluminum alloy. One can notice the negative radial forces arising due to the changes in the

Fig. 1 Effect of cutting speed on cutting force for five aluminum alloys^[2]

Fig. 2 Variation of cutting forces with effective side cutting edge angle during a contour turning Operation using (a) flat-faced tools; and (b) grooved tools^[3]

effective geometry of the cutting tool. The large changes in the cutting forces along the contour profile result in varying chip flow and consequently varying chip-form. This is discussed in greater detail in the section on chip-form/chip breakability (see “Chip Form/Chip Breakability” section).

The variation in cutting forces when machining with carbide tools and PCD tools has been investigated by König.^[4] Figure 3 shows a plot of this comparison; it is observed that the forces in machining with PCD tools are much lower and that the machining is done at much higher cutting speeds.

One of the recent technological advances in machining methods has been the use of ultrasonic vibration machining.^[5] This research work investigated the high silicon content A390 alloy which is typically hard to machine due to the widespread content of abrasive silicon. This alloy is generally used in the manufacture of engine blocks and air compressor cylinders due to their high wear resistance, low density and high strength at elevated temperatures. Figure 4 shows the variation of cutting forces as functions of (a) cutting speed; (b) depth of cut;

Fig. 3 Variation of cutting forces in turning of aluminum alloy (GK-AlSi17Cu4FeMg) with carbide and PCD tools^[4]

and (c) feed rate when using conventional and ultrasonic vibration methods.

Tool-Life/Tool-Wear

Tool-life and tool-wear are very important criteria for assessing the machining performance when machining aluminum with carbides and HSS tools. However, with the widespread use of diamond-based tools, the tool-life problem has been alleviated to a great deal. König^[4] in his work on machinability of cast aluminum alloys has clearly shown the quantitative advantages of using diamond-based tools (in this case, PCD tools) as compared with conventional carbide tools (Fig. 5). There is also strong evidence of the negligible role of the machining operation on the tool-life when machining aluminum alloys; the tool-life was very similar for turning and face milling operations [Fig. 6(a) and 6(b)]. Typically, tool-life is very much dependent on the silicon content in the work material. This corresponds very well with the higher cutting forces that are necessary for the machining of hypereutectic alloys. Also, the sticky nature of aluminum alloys tends to cause a build-up of material on the cutting tool thereby reducing the tool-life although without considerable wear of the tool.

A comparative study of dry machining of aluminum alloys by using uncoated carbide tools, PCD tools and

CVD diamond tools has revealed the importance of selecting the suitable tool material in order to attain the “best” tool-life and consequently a high level of machining performance.^[6] In order to compare the wear characteristics between the uncoated cemented carbide tool and the CVD diamond-coated tool, the machining was performed on a low silicon content aluminum alloy (A380 with 8.5% Si). However, to compare the PCD tool’s performance with the CVD diamond tool, the machining was carried out on a high silicon content aluminum alloy (A390 with 17% Si) since carbide tools cannot be used when machining high silicon content aluminum alloys. The plots showing the flank wear over the cutting time for the machining of A380 and A390 alloy are shown in Fig. 7(a) and 7(b) respectively. It can be seen that the CVD diamond-coated tool performed exceptionally well when compared with the uncoated carbide tool. The excellent performance of the CVD diamond-coated tool was attributed to the outstanding mechanical properties of the diamond coating and the strong adhesion to the carbide substrate. Since the A380 alloy has comparatively low silicon content, the abrasive action of silicon is not present and the CVD diamond tool suffered hardly any tool-wear. It can be seen that the CVD diamond tool also performed very well when compared to the PCD tool when machining the more abrasive and tough-to-machine A390 alloy. The failure of both tools

Fig. 4 Variation of cutting forces with (a) cutting speed; (b) depth of cut; and (c) feed, when machining A390 alloy using conventional and ultrasonic vibration methods^[5]

was attributed to abrasive wear mechanisms. However, the PCD tool provided a much better degree of surface finish when compared to the CVD diamond-coated tool.

Chip Form/Chip Breakability

Chip form and chip breakability are very strong indicators of the degree of machining performance that is achieved.

A thorough, state-of-art research work which explains the role of chip control in machining has been recently produced under the sponsorship of CIRP.^[7] A very effective method of observing the effect of machining parameters, depth of cut and feed, is in the form of a chip chart. Figure 8(a) and 8(b) shows representative chip charts for the machining of Aluminum alloy 6061 with two different nose radii of 0.4 mm and 0.8 mm.^[8] Specifically related to aluminum and its alloys, chip control has been a vexing issue, especially due to the typical snarled and stringy chips that aluminum machining produces.

The final chip-form results from the direction of chip flow, the chip curl radius and the bending moment caused by the free-end of the chip anchoring on the tool flank or the rotating workpiece, thereby causing the chip to break. The chip-groove configurations on tools force the chip to curl tightly and enable it to effectively break into a small size. Typical areas wherein chip control can be a problem are in finish machining of components with complex contours, e.g. the wheel rims of automobiles. The finish cut during such operations involves machining along a contour. This results in a continuously varying depth of cut and a relative continuously changing tool geometry. In order to obtain a better understanding of the complex chip flow mechanism in contour turning of aluminum alloys, Blasius^[3] performed experiments with 2011-T3 aluminum alloy with a PCD flat-faced tool and a CVD diamond coated grooved tool. The work contour was experimentally designed to provide continuously varying machining parameters and tool geometry. The chip side-flow angle was measured by using a high speed filming system which operated at 1000 p.p.s. [Fig. 9(a) and 9(b)]. The surface roughness obtained from machining using the two different cutting tool inserts was also measured.

Chip-form and chip breakability are greatly influenced by the type of aluminum alloy used and its material properties. The aluminum alloy 2011 is a high strength and free cutting alloy which exhibits excellent machinability. It provides excellently broken chips thereby exhibiting a strong degree of chip control, in addition to excellent surface quality and low tool-wear rates. Alloys such as 2024-T4 and 2017-T4 tend to produce continuous chips, thereby necessitating the use of a chip-breaker geometry on the cutting tool insert. The CVD diamond-coated tool inserts with chip-breaker geometry are ideally suited for ensuring a high degree of chip control with these materials. Alloys such as 6061-T6 and 5056-H38 are comparatively more difficult to machine and produce sharp and stringy chips which are difficult to break. Soft alloys such as 5052, 3003 and 1100 tend to produce more soft and gummy chips, thereby necessitating careful selection of chip-breaker geometries and tool coatings.^[1]

In an investigative case study on trouble shooting of uncontrollable chips, Maekawa et al.,^[9] studied the machining of aluminum heat rollers. The cutting conditions used are shown in Table 3. Six different types of tool

inserts and tool geometry were used in the analysis. The details of these tool inserts and geometry are provided in Table 4. The resulting chip morphology at the various combinations of cutting conditions and tool geometry are provided in the form of a chip chart in Fig. 10. It can be seen that the tool geometry of Cases 5 and 6 and the cutting conditions corresponding to Case (c) (see Table 3) provided the best degree of chip control for the machining operation. This case study shows the importance of selecting the right tool geometry (especially the chip-groove geometry and the tool angles).

Case Study: Change in Material Improved Chip Breakability Performance

The hydraulic division of Parker Hannifin improved machining performance by obtaining better chip control when they replaced the conventional Al 6061-T6511 extruded aluminum alloy with the cold finished Al 6013-T8 aluminum alloy for production of hydraulic valve blocks.^[10] The 6013-T8 alloy produced small, well broken chips, thereby negating continuous monitoring for chip control problems. In addition to better chip control, the new material possessed 50% higher strength than the extruded 6061 alloy and provided anodizing and corrosion resistance comparable to the 6061 alloy. The excellent degree of chip

Fig. 5 Comparison of tool-life in turning of aluminum alloy (GK-AlSi17Cu4FeMg) with carbide and PCD tools^[4]

Fig. 6(a) Comparison of tool-life in turning^[4]

Fig. 8 Chip charts showing effect of varying nose radius (a) $r_n = 0.4$ mm and (b) $r_n = 0.8$ mm on resulting chip-form when machining of Aluminum B6061 alloy^[8]

control provided by this material also improved other performance measures such as surface quality and resulted in the capability to machine to finer tolerances. The overall machining productivity improved by 15–25% due to the selection of the 6013 alloy with great reductions on the deburring required for the finished part.

Surface Roughness/Surface Integrity

Surface roughness and surface integrity are important performance measures which indicate the performance level attained by using the particular work material-tool material combination and the corresponding suitable

Fig. 9 Variation of chip side-flow angle with the effective side cutting edge angle in contour turning of Al6061 with (a) flat-faced inserts; and (b) grooved inserts^[3]

feeds, speeds and depth of cut. The importance of considering surface roughness/surface integrity when machining Aluminum and its alloys arises due to the high thermal conductivity and low melting temperatures. This can result in considerable deformation to the generated surface.

Table 3 Cutting conditions for machining of aluminum heat rollers^[9]

	Case (a)	Case (b)	Case (c)
Cutting speed (m/min)	375	375	375
Feed (mm/rev)	0.5	0.25	0.35
Depth of cut (mm)	0.5	1.0	1.0

The residual stress induced in the machined work material has been used as a significant measure of the surface integrity. Considerable work has been done by researchers on the generation of residual stresses when machining aluminum alloys.^[11–13] The effects of the cutting speed on the residual stresses at various nose radii, feeds and depths of cut respectively, when machining aluminum alloy 2014 are shown in Fig. 11(a), 11(b) and 11(c).^[14] One can see that in all three cases the least peak residual stress occurs at the middle of the tested range, indicating the need for considering this type of a non-linear optimum when selecting the tool geometry and cutting conditions in order to minimize the effect of the residual stresses. It can also be seen that the depth of cut plays a very minor role in influencing

Table 4 Tool geometry used in machining of aluminum heat rollers^[9]

Case #6		

the residual stresses induced in the surface of the machined material. The microstructure of the machined surface for the 3014 aluminum alloy at a feed rate of 0.1 mm/rev and 0.2 mm/rev is shown in Fig. 12(a) and 12(b).^[14]

The relationship between the surface roughness and the cutting parameters such as cutting speed, axial and radial depth of cuts and the feed rate was investigated in high-speed machining of aluminum with a diamond and a sintered carbide end-mill.^[15] The results of this study

are shown in the plots in Fig. 13. It can be seen that the diamond end-mill far outperformed the carbide end-mill as far as performance in terms of surface roughness. The relative quality of the surfaces produced by the carbide end-mill and the diamond end-mill can be seen in Fig. 14, where the diamond end-mill provides almost near perfect reflective surface quality.

The role of advanced technology such as ultrasonic vibration cutting was discussed earlier in “Cutting Force/Power/Torque” section. The comparison of surface roughness as a function of cutting speed is provided in Fig. 15(a). The conventional and ultrasonic methods were compared with both a PCD tool and a SCD (single crystal diamond) tool when machining A390 alloy. The SCD tool far outperformed the PCD tool but is not an economic alternative. The variation of the surface roughness with respect to the depth of cut and the feed rate is shown in Fig. 15(b) and 15(c) respectively. The ultrasonic method tended to provide better results in terms of surface roughness just as it did in the case of cutting forces. However, this technology is yet to be tested at a major level on industrial platforms to see its true benefits for large scale production.

General Case Study: Machining Performance Evaluation of Hypereutectic Al-Si Alloys

As mentioned earlier in “CLASSIFICATION OF ALUMINUM AND ITS ALLOYS FROM A MACHINING STANDPOINT” section, hypereutectic aluminum alloys are finding niche applications in the automotive industry due to their high resistance to deformation at high temperatures, resistance to wear and the advantageous strength-weight ratio. However, the excellent resistive properties of this material also make it very difficult to machine. The high content of hard silicon crystals contributes a great deal making it difficult to machine. Weinert et al.^[16] in a recent study have examined the machining performance of hypereutectic aluminum alloys in a heat treated (T6) and a non-heat treated condition with varying cutting materials and cutting conditions. The machining performance

Fig. 10 Chip morphology at various combinations of cutting conditions and tool geometry^[9]

Fig. 11 Variation of the residual stress with cutting speed at varying (a) tool nose radii; (b) feeds; and (c) depths of cut when machining Aluminum 2014 alloy^[13]

measures used for assessing the machining performance were tool-wear and surface quality. The range of cutting speeds used in the study varied from 200 to 400 m/min. This study concluded that the CVD diamond-coated tools and the PCD tools exhibited excellent wear resistance, whereas carbide tools coated with titanium nitride

Fig. 12 Microstructure of the machined surface of Aluminum 2014 alloy at (a) feed=0.1 mm/rev. (magnification=400×); and (b) feed=0.2 mm/rev. (magnification=100×) (depth of cut=3 mm, flank wear=0.1 mm, cutting speed=125.7 m/min. and tool nose radius=0.4 mm)^[14]

performed very poorly due to high wear-rates. Figure 16 shows the SEM pictures of four cutting tools after 750 sec of cutting time: (a) uncoated carbide; (b) coated carbide (titanium nitride coating); (c) diamond-coated onto carbide substrate; and (d) polycrystalline diamond (PCD) tool. Figure 17 shows the different widths of the wear land VB for the different cutting tools and their dependence on cutting time t_c . A comparative analysis of cemented carbide tools and the different grain sizes showed that the larger grain size improved resistance to tool-wear. The performance study on the surface roughness showed that surface quality depended primarily on the cutting tool composition and the wear conditions of the tool. The PCD tool gave the best surface quality ($R_z=2-3\mu\text{m}$) and the coated and uncoated carbide tools gave R_z of around $3-6\mu\text{m}$. An investigative analysis of the surface integrity of the heat-treated alloys (machined material) with a SEM showed no metallurgical changes in the material. The analysis of the non-heat-treated alloy showed that severe plastic deformation, cracks and breaks in the hard phases were observed when machining with the carbide tools. The analysis with a PCD tool showed minimal damage to the surface microstructure. The representative SEM micrographs showing the sub-surface microstructure when machining with carbide tools and PCD tools are shown in Fig. 18.^[16]

Fig. 13 Variation of surface roughness with (a) cutting speed; (b) axial depth of cut; (c) radial depth of cut; and (d) feed per tooth during high-speed machining of Aluminum 2024 alloy with a diamond and sintered carbide end-mill^[15]

THE CUTTING TOOL

The selection of the most appropriate cutting tool is a major selection decision for a process planner when planning for the machining of an aluminum alloy. Additionally, there has to be a decision on the necessity of a coating (especially

for carbides) as well as the presence of a chip-groove for breaking the “stringy” chips typical of finish machining of aluminum alloys. The use of carbides for machining of aluminum alloys is slowly fading out. Even with a tool coating, the tool-wear rates compare very inferiorly with that of the more effective diamond-based tools. Unless the machine tool cannot operate at the recommended high speeds for diamond-based tools, the usage of carbide tools is not recommended. Diamond tools and coatings exhibit ideal properties for the machining of non-ferrous alloys. The most suitable of these properties are:

- high hardness
- low coefficient of friction
- high thermal conductivity

There exist two major classes of diamond-based tools:

1. Polycrystalline diamond (PCD) tools.
2. CVD diamond coated tools.

Polycrystalline diamond tools have been in use for almost 40 years. These tools are manufactured by brazing a PCD tip onto a substrate such as carbide. However, this type of tool manufacture restricts the usage to just one cutting edge per insert. The CVD diamond coated tools are available typically in two sub-classes; with thick and thin coatings. The thin film diamond coating is applied directly to the substrate material whereas the thick film diamond coating is grown, polished and then brazed onto the substrate material.

Recent tests by a prominent toolmaker (Kennametal, Inc.) have shown that tools with a CVD coating (approximately 30 μm thick) equaled or exceeded the tool-life of comparable PCD tools, depending on composition and microstructure of the work material.^[17] However, the PCD tool provided a better surface finish. In terms of tool-life, the PCD and thick CVD diamond coated tools provided excellent tool-life but a poor degree of chip control. The thin CVD diamond-based tools offer the advantage of easy applicability on to a tool with an effective chip-breaker design, thereby providing added chip control benefits.

The higher cost of diamond-based tools is offset by the higher productivity due to operation at high cutting speeds (ranging from 500 to 2500 m/min) and the better quality of the machined surface. However, when machining hypoeutectic alloys with a solid PCD tool, chip control is a big problem. In these cases the use of a CVD diamond-coated tool with a chip breaking groove is highly recommended. This type of cutting tool insert provides the advantage of a diamond tool with the effectiveness of good chip breaking. In the case of hypereutectic alloys, the abrasive particles of silicon embedded in the work material serve as a natural chip breaker, and in many cases a solid PCD tool can be used for effective machining of such alloys.

Fig. 14 Relative surface quality obtained by using a diamond end-mill and a sintered carbide end-mill during milling of Aluminum 2024 alloy (cutting speed=377 m/min., feed/tooth=0.00038 mm/tooth, radial depth of cut=6 mm, axial depth of cut=0.04 mm).^[15]

HIGH SPEED MACHINING OF ALUMINUM ALLOYS

High speed machining is one of the fast growing technological areas closely related with the machining of light metal alloys. High speed machining has several advantages apart from the obvious increase in machining productivity and these include:^[18]

- increased machining accuracy, especially in the manufacture of parts containing thin webs
- better surface finish and reduction in the damaged layer
- reduced burr formation
- better chip disposal
- possibility of higher stability due to superposition of stability lobes against chatter vibration

Since the typically used diamond tools have excellent tool-life characteristics, tool-life is not a limiting factor in the high speed machining of aluminum alloys. Advances in machine tool structural technology and control systems have enabled the production of dedicated machine tools capable of effectively using high speed machining. Chip removal rates can be increased by five times in high-speed roughing and finishing of aluminum alloys. The recommended machining parameters for wrought aluminum alloys are a cutting speed of 4700 m/min. For cast hypoeutectic alloys (< 12% Si), CVD diamond coated chip-breaker tools are highly suitable at cutting speed of 1300 m/min. The high speed machining of cast hypereutectic alloys (> 12% Si) requires the use of PCD tools with cutting speeds of 1200 m/min.

Recent research work^[15] has shown the remarkable improvement of surface quality and the reduction in

built-up edge and burr formation when performing high speed milling with diamond end mills. Figure 19 shows the advantages of using high speed machining with diamond end mills as compared to conventional milling methods. Also, previously shown in Fig. 14 are the contrasting results obtained in surface quality by high speed machining with diamond tools as compared with conventional carbide tools. The excellent surface quality obtained from such high speed machining negated the necessity of using a finishing process such as lapping or polishing. They also determined that the most critical parameter affecting the surface quality was the axial depth of cut.

Case Study: Machining of Thin Web Structures for Boeing's 737 Aircraft

High speed machining has been used very effectively in the production of thin web aluminum alloys stringers which assemble onto the Boeing 737 aircraft. Stringers are long, horizontal members to which the aircraft's aluminum skin is riveted. Spindle speeds upto 25000rpm were used in the drilling of the holes for the stringers. A dedicated fixturing system had to be designed for performing the high speed machining.^[19]

DRY MACHINING

Dry machining of advanced materials is being widely promoted in the manufacturing industry. The major reasons for shifting towards dry machining are:

1. environmental concerns over disposal of cutting fluids and the damage they cause to the environment

Fig. 15 Variation of surface roughness with (a) cutting speed; (b) depth of cut; and (c) feed when machining A390 alloy with conventional and ultrasonic methods^[5]

2. economic factors
3. health hazards to operators due to wet machining

A recent study by Daimler Benz showed that up to 16% of the total production cost is coolant related.^[20] There has been a renewed initiative in German industries to aim for dry or “nearly dry” machining. The U.S. Council for Automotive Research’s Partnership for a New Generation of

Fig. 16 SEM photographs of four cutting tools after 750 sec of cutting of hypereutectic Al-Si alloys: (a) uncoated carbide (VB=0.056 mm); (b) titanium nitride coated carbide (VB=0.065 mm); (c) diamond coated carbide (VB=0.037 mm); and (d) polycrystalline diamond PCD (VB=0.02 mm); (Work material = AlSi25X, cutting speed = 400 m/min., feed = 0.1 mm/rev., depth of cut = 1.0 mm, tool nose radius = 0.8 mm)^[16]

Vehicles (PNGV) has targeted dry machining of aluminum as one of the major focus areas for further research leading to development of new tools and materials, and development of innovative systems for optimal chip formation, ejection and disposal.^[21]

Aluminum alloys are extremely critical to the subject of dry machining. Typically, the problems associated with dry machining of aluminum alloys arise from the high level of thermal conductivity of the work material thereby leading to surface deformation. The other very significant problem arises from the adhesion of the work material onto the cutting tool, which resulted in ending of the tool-life. In a recent CIRP keynote paper, the most critical aspects to be considered in the dry machining of aluminum alloys are discussed.^[22] It is suggested to use MQL (minimum quantity of lubricant) to offset the problems in pure dry machining of aluminum alloys. The positive effect of using MQL when machining aluminum alloys is shown in Fig. 20. It is also recommended that PCD inserts or more preferably diamond-coated inserts with a chip-groove be used for effective machining of aluminum alloys. The use of a chip-groove causes considerable difference in the level of chip control that is attainable, especially for breaking the stringy chips which are very typical of aluminum machining.

In a recent study of industrial perspectives on dry machining, it was suggested that for machining aluminum, near-dry machining with minimal coolant consumption is a promising approach.^[23] A metered supply of biodegradable oil drops at the cutting edge through a nozzle in the tool aids in effective machining of aluminum with large savings in lubricant consumption and environmental damage.

Fig. 18 Representative SEM micrographs showing the sub-surface microstructure after machining of hypereutectic Al-Si alloy (AlSi25X) with (a) uncoated carbide; and (b) PCD tools^[16]

However, in terms of tool-life, wet machining still provides better tool-life. This can be seen in Fig. 21^[1] wherein there is a comparison of dry turning with wet turning

Fig. 19 Advantages of using high-speed diamond milling over conventional milling and plain high-speed milling^[15]

when using diamond and carbide tools. Table 5 provides a list of common cutting fluids used for machining aluminum. The cutting fluids used however need to be reduced scientifically to attain MQL in order to provide better machining performance without undergoing the hazards of truly wet machining.

MACHINING OF ALUMINUM-BASED METAL MATRIX COMPOSITES (MMCS)

One of the major developments which has provoked the necessity of a revised material selection process by designers and manufacturers has been the introduction of metal matrix composites (MMCs). These MMCs are finding niche areas for application wherein they are replacing traditional materials. MMCs have advantages over other fiber-based composites and their wear resistance and lightness make them very suitable in automobile body parts such as brake drums and rotors. The MMCs typically comprise of aluminum matrix composites reinforced by either of the following:

- continuous fibers (boron, silicon carbide, alumina, graphite)
- discontinuous fibers (alumina, alumina-silica)
- whiskers (silicon carbide)
- particulates (silicon carbide, boron carbide, alumina, etc.)

MMCs are renowned for their high specific strength, high wear resistance but poor machinability. The major problem associated with MMCs containing silicon carbide is the difficulty in machining due to the presence of the hard and

Fig. 21 Comparison of tool-life when dry turning and wet turning of sand cast alloy 390 with carbide and diamond tools^[1]

abrasive silicon carbide or other reinforcement materials. Correspondingly, the major focus of research on the application of MMCs has been directed towards the following two areas:

1. Establishment of machinability parameters and scientific selection procedure for tool inserts and cutting conditions for the MMCs.
2. Assessing the effect of reinforcement directions on the machining performance of such MMCs.

The literature on machinability of the MMCs is very limited in content. Machining performance measures such as the cutting force, torque and tool-wear were studied during the drilling and reaming of aluminum alloys and MMCs by using a PCD tipped tool.^[24] The MMC (containing

Fig. 22 Flank wear results from drilling experiments on Al-Si alloys and MMC using PCD tipped drills^[24]

Table 5 List of cutting fluids for machining of aluminum and its alloys^[1]

Type of lubricant	Principal ingredients	Viscosity range	Application; maintenance	Relative effectiveness	Necessary precautions
Mineral oils (fatty-additive type preferred)	Mineral oil, lard, or neatsfoot oil; oleic acid or butyl stearate	40 SUS at 40°C (100°F) for high-speed machining to 300 SUS for low speeds	Generous flow at all cutting edges; keep recirculating fluid clean and cool.	Good lubricity and chip flushing; fair cooling; excellent finish as built-up edge is minimized	Control air above oil where mis application endangers shop air; remove oil from finished parts (also from chips to reclaim and reduce fire hazard).
Soluble oils (emulsions) (3–5% soluble oil in water)	Soluble oil, petroleum sulfonate emulsifying agents, water (oil is added); rust inhibitor, germicide, stain inhibitor	Generally low	Generous flow at all cutting edges; keep recirculating fluid clean; cool when necessary.	Good chip flushing; lubrication adjustable by varying concentration; excellent cooling; good finish	For high-speed machining cooling is more important than lubrication; where emulsion is applied as mist, keep oil content as low as possible to reduce air and shop contamination.
Aqueous chemical solutions	Water; soluble synthetics (usually clear); sometimes, fatty materials; rust inhibitors; germicides	Generally low	Generous flow at all cutting edges; keep recirculating fluid clean; cool as required.	Good chip flushing; excellent visibility of cut; excellent cooling; adjustable lubrication; good finish	Keep oil content low; control mist; consider cost (significantly higher than soluble-oil emulsions).
Stick lubricants	Mineral compounds, animal fats, waxes, synthetics	Various hardnesses	Applied as required to blades, wheels, disks, or files or to workpiece	Prevents the loading of abrasive surfaces or of teeth of saws and files	Applied is intermittent, but should be monitored and made as required throughout run

Fig. 23 Experimental results from drilling of Al-Si alloys and MMCs with PCD tipped drills showing the variation of (a) thrust force, and (b) torque with number of holes drilled^[24]

Fig. 24 Comparative tool-life produced by different tool materials when facing Al-Li SiC_p MMC (depth of cut=0.5 mm, feed=0.07 mm/rev., dry machining)^[25]

silicon carbide particulates) produced the largest tool-wear whereas the hypoeutectic alloy (with low silicon-content) produced the lowest tool-wear (Fig. 22). It can also be seen that the MMC produced the larger cutting force [Fig. 23(a)] and the largest torque [Fig. 23(b)] when using the PCD tipped drill. Hung et al.^[25] have researched the machining performance of silicon carbide-based MMCs by using tool-wear as a machining performance indicator. They tested a variety of tool materials (ranging from high speed steel to polycrystalline diamond (PCD)) and concluded that cubic boron nitride (CBN) and PCD tools fractured the silicon carbide particles along their crystallographic planes and thereby induced little damage on the MMC matrix, whereas the other tools delaminated the particles from the matrix, further roughened the particles and also significantly deformed the MMC matrix. Figure 24 shows the comparative tool-life given by the different tool materials when facing Al-Li SiC_p MMC. The comparative pictures showing the sub-surface deformation undergone by the machined material when using the carbide tool and the diamond tool is clearly shown in Fig. 25 (a) and (b).

The critical role of tool-wear in the machining of MMC's has been discussed already. The reinforcement materials which are very hard, cause severe abrasive wear of the tool materials. The higher the hardness of the

Fig. 25 Sub-surface plastic deformation of 20% Al-Li SiC_p MMC due to facing with (a) a carbide tool; and (b) a diamond tool^[25]

reinforcement material, the higher the tool-wear. Figure 26 shows the tool-wear (flank wear VB) when machining (a) silicon carbide and (b) boron carbide reinforced aluminum MMC's with PCD tools.^[26] It can be seen that just 10% of boron carbide (B₄C) induces higher tool wear at a cutting speed of 250 and 500 m/min. Until the severe problems of abrasive tool-wear during the machining of MMCs is not solved, the overall machining performance cannot

Fig. 26 Tool-wear when turning (a) 20% SiC reinforced aluminum; and (b) 10% B₄C reinforced aluminum with a PCD tool^[26]

improve. Considering the many advantages of MMCs, the research community needs to address the issue of higher cutting forces (to a lesser extent) and the high degree of abrasive tool-wear in order for promoting more widespread use of MMCs in industrial practices.

SUMMARY

The review and analysis presented in this chapter on machining of aluminum and its alloys indicates the growing industrial trend in the application of machined parts and the associated technological challenges involved in

achieving “optimum” machining performance. The role of new cutting tool development and the related machining applications are also presented in this chapter. Emerging areas of research and applications are identified, and this includes high speed machining, dry machining and machining of aluminum-based MMCs. The advantages of pursuing high speed machining have been highlighted with experimental results and a case study. Currently, the use of MQL (minimum quantity of lubricant) machining has found to be more favorable over purely dry machining of aluminum from the machining performance standpoint. Further research is necessary for approaching effective pure dry machining of aluminum alloys. The advantages of using aluminum-based MMCs has been counterbalanced by the poor machinability exhibited by them. The issue of high cutting forces and accelerated tool-wear during machining of aluminum-based MMCs needs to be researched more thoroughly before they can be used on a large scale. Automotive and aerospace applications of aluminum alloys have in recent years strengthened the need for future research and partnership among the various industry groups and universities/research institutions.

Master Alloys for Grain Refinement

Xiaoming Wang

Purdue University, West Lafayette, United States

Abstract

Master alloys are routinely added into aluminum melts before casting for grain refinement purposes. The widely used master alloys contain titanium and boron in the forms of Al_3Ti and TiB_2 particles in an aluminum matrix. Upon addition into aluminum melts, Al_3Ti dissolves into the aluminum melts and promotes the heterogeneous nucleation of the α -Al grains while restricting the growth of α -Al grains through a constitutional cooling effect in solidification. Meanwhile, TiB_2 is stable and acts as a substrate for the heterogeneous nucleation of α -Al grains through a layer of Al_3Ti on the surface. Sharing these in common, different mechanisms for the grain refinement of aluminum by Al-Ti-B-type master alloys have been proposed. Another kind of popular master alloys is Al-Ti-C, which is used in a lesser extent for the grain refinement of Al alloys containing elements that are poisoning Al-Ti-B master alloys. Titanium and carbon exist as Al_3Ti and TiC particles. TiC is not as stable as TiB_2 and decomposes in aluminum melts. TiC in Al-Ti-C therefore acts as heterogeneous nucleation sites for α -Al grains similar to TiB_2 . However, the fading of Al-Ti-C master alloys is irreversible, which is the major disadvantage of Al-Ti-C master alloys. Al-Ti master alloys do not contain hard particles and are used industrially for products that are sensitive to hard TiB_2 and TiC particles. There are also other master alloys that show high grain refinement potentials in lab tests but have never been used industrially for mainly low-volume production and high costs. This article gives an overview of the grain refinement of aluminum by master alloys with an emphasis on Al-Ti-B master alloys, from the production to the industrial applications of the master alloys.

Keywords: Al_3Ti ; Al-5Ti-1B; Al-Ti; Al-Ti-B; Al-Ti-C; Aluminum; Casting; Grain refinement; TiB_2 .

INTRODUCTION

As shown in Fig. 1, equiaxed, columnar, and twined columnar grains can be produced in aluminum castings depending on the constitution and processing of aluminum alloys, particularly solidification conditions.^[1–3] It is critical to control the aluminum grain size and morphology because of their huge impact on the properties of the castings and follow-on processing, e.g., rolling, forging, and extrusion. Columnar and twined columnar grains result in reduced mechanical properties, such as reduced yield strength and tensile elongation, a variety of surface defects, and hot cracking in the shell zones of direct chill (DC) casting ingots. To reach a high casting speed before hot cracking is encountered meanwhile to offer increased mechanical properties, equiaxed grains are desirable. The beneficial effects of grain refinement on shape castings include uniform mechanical properties, homogeneous dispersion of secondary phases and microporosity, better feeding, less shrinkage porosity, and better surface finish.^[1] It is an industrial practice to introduce inoculants into aluminum melts before casting to promote the formation of equiaxed grains and to suppress the formation of columnar or

twined columnar grains in aluminum castings, i.e., grain refinement.^[1,4–9]

Al-Ti-B master alloys are widely used in the aluminum casting industry to produce fine equiaxed α -Al grains ($\sim 220 \mu\text{m}$).^[1,5,9,10] The master alloys contain numerous stable TiB_2 particles in size of a few micrometers acting as heterogeneous nucleation sites for α -Al grains in solidification. Meanwhile, titanium in solution due to the dissolution of Al_3Ti particles both promotes the heterogeneous nucleation and restricts the growth of α -Al grains. The grain refinement of aluminum by adding Al-Ti-B master alloys can be dated back to the systematical study of the reduction of α -Al grain sizes by adding different alloying elements into aluminum melts before casting, including Ti and B.^[4] Earlier work on the effects of titanium on grain refinement can also be found though not being credited generally. The conversion of coarse columnar grains to fine equiaxed grains of aluminum through grain refinement not only leads to better mechanical properties but also makes cold working possible. Otherwise, cracks form at the grain boundaries of large columnar aluminum grains in cold processing, leading to failure. Constant efforts, therefore, have been made to understand the grain refinement mechanisms

Fig. 1 The grain structures of an Al-2.5wt% Mg alloy, (a) showing equiaxed grains after the addition of Al-5Ti-1B master alloy; (b) columnar grains and (c) twinned columnar grains without the addition of master alloys

aiming at improving the grain refinement efficiency of the master alloys and the development of new types of master alloys.^[1,5,6,9–19]

A widely used Al-Ti-B master alloy contains 5wt% Ti and 1wt% B, called Al-5Ti-1B in the following paragraphs, in forms of Al_3Ti and TiB_2 particles. As shown in Fig. 2, a typical as-cast microstructure of Al-5Ti-1B master alloys, Al_3Ti particles are situated in the α -Al grain centers, whereas TiB_2 particles are located at the α -Al grain boundaries in this low-magnification backscattered electron image under a scanning electron microscope (SEM). The sizes of Al_3Ti particles are hundred times larger than that of TiB_2 particles, which agglomerate together mainly along the α -Al grain boundaries. After addition into an aluminum melt, it gives an overall concentration of 0.01 wt% Ti and 0.002 wt% B in aluminum castings, which effectively reduces the aluminum grain size down to a few hundred micrometers.^[1,5] The grain refinement performance of Al-Ti-B master alloys is affected by many factors, such as microstructure of the master alloys, different processing histories, and impurity of the aluminum melt. Master alloys with the same composition but from different manufacturers or made from different processes do not have the same grain refinement efficiency. The relationship between the microstructures of master alloys and their grain refinement performances has been studied extensively.

Investigations into the microstructure of Al-Ti-B master alloys, mainly on phase formation and phase relationships between Al_3Ti and TiB_2 , and their dispersion inside the master alloys, have revealed that Al_3Ti particles can be produced in different morphologies through adjusting the processing temperature and cooling rate, leading to different grain refinement efficiencies attributed to their different dissolution characteristics. The formation of Al_3Ti particles is also affected by the presence of TiB_2

particles, which act as substrates for the nucleation and growth of Al_3Ti particles.^[8] Large Al_3Ti particles in Fig. 2 are identified at a high resolution by SEM as duplex particles of Al_3Ti - TiB_2 with certain crystal orientation relationships between these two phases.^[9,19–22] The morphology of duplex Al_3Ti - TiB_2 particles may alter the dissolution behavior of the Al_3Ti leading to different grain refinement performances, in terms of contact time and fading rate. However, TiB_2 particles are always in a hexagonal disk shape, and the morphology of TiB_2 particles is not affected by the production conditions of the Al-Ti-B master alloys apparently.

Al_3Ti particles dissolve in an aluminum melt producing solute Ti, whereas TiB_2 particles remain solid after Al-Ti-B master alloys are added into an aluminum melt. It is generally accepted that TiB_2 particles nucleate aluminum grains in solidification as heterogeneous nucleation substrates despite the dispute on how it is realized.^[23] In fact, Ti and B in an atomic ratio of 0.5, i.e., the stoichiometry of TiB_2 , does not nucleate α -Al grains at all.^[17] The nucleation of α -Al grains on TiB_2 particles therefore involves solute Ti both from the dissolution of Al_3Ti particles in the master alloys and impurity Ti from aluminum electrolysis or recycling. A peritectic reaction exists in an Al-Ti phase diagram, indicating the ease of aluminum grains nucleating on an Al_3Ti phase.^[7] In the presence of more stable TiB_2 particles, a heterogeneous nucleation of Al_3Ti on the TiB_2 particles becomes more likely due to the higher melting point of Al_3Ti than that of aluminum. However, the peritectic reaction consumes solid Al_3Ti to form a solid solution of titanium in α -Al. There is no industrial evidence of Al_3Ti in aluminum castings that have been grain refined by Al-Ti-B master alloys. Specially designed experiments by adding TiB_2 particles and a high concentration of titanium demonstrated the formation of Al_3Ti on TiB_2 particles and nucleated α -Al grains.^[17] However,

Fig. 2 A typical microstructure of Al-5Ti-1B master alloy

these results have failed to attract a great attention from the scientific society as duplex $\text{Al}_3\text{Ti-TiB}_2$ particles have been observed in master alloys all the times.^[9,21] Based on these considerations and other designed experiments, different grain refinement theories have been proposed.^[8,10,19,22]

The grain refinement of aluminum by master alloys has been studied for nearly a century. Numerous findings and proposed theories have been presented in open literature. However, a consensus about the grain refinement mechanism is still not reached. This article summarizes the published results with a critical review aiming at providing fundamental information about the application of master alloys in grain refinement of aluminum and therefore guiding the development of more effective master alloys and industrial practice of aluminum grain refinement by using master alloys.

MASTER ALLOYS

Master alloys are added into an aluminum melt to promote the nucleation of $\alpha\text{-Al}$ grains and to depress their growth in solidification, leading to the formation of fine equiaxed $\alpha\text{-Al}$ grains.^[1,6,10,13,15] Heterogeneous nucleation of $\alpha\text{-Al}$ grains is realized by the introduction of stable TiB_2 particles in Al-Ti-B master alloys, while solute Ti from the dissolution of Al_3Ti particles promotes the heterogeneous nucleation and depresses the growth of the $\alpha\text{-Al}$ grains. The final concentration of titanium and boron in an aluminum melt must be controlled carefully to avoid either agglomeration of the TiB_2 particles or the formation of large size duplex $\text{Al}_3\text{Ti-TiB}_2$ particles. Al-Ti-C is another type of master alloys with advantages of lack of hard TiB_2 particles in castings and immune to poisoning of certain alloying elements, such as Zr and Si that are poisonous to Al-Ti-B master alloys otherwise.^[5,10,24–27] Al-Ti-C master alloys also improve castability and increase filter bed life in DC casting. However, TiC particles decompose slowly into Al_4C_3 particles, which grow with holding time leading to the degradation of Al-Ti-C master alloys in grain refinement.^[28]

Al-Ti-B master alloys are produced via chemical reaction of K_2TiF_6 and KBF_4 with molten aluminum. Possible chemical reactions are shown in Eqs. 1–3. TiB_2 , Al_3Ti , and their mixtures can be produced through adjusting the K_2TiF_6 to KBF_4 ratio, i.e., the Ti/B ratio in the master alloys. However, AlB_2 is always observed together with TiB_2 particles as either a mixture of the two individual phases or a solid solution of them, which is still under dispute. The phase formation and composition of the particles are largely affected by processing histories. The grain refinement performances of the master alloys that have been produced through different processes are hugely different. And a minor change in the production of master alloys leads to a big change in their grain refinement performance.^[1] Therefore, a lot of effort has been devoted

to understanding the formation of the ceramic particles in Al-Ti and Al-Ti-B master alloys and their performance in aluminum grain refinement.^[16,20,21,29]

As shown in Fig. 2, a typical microstructure of Al-5Ti-1B master alloys, large blocky Al_3Ti particles are identified in the $\alpha\text{-Al}$ grain centers under SEM. It is a strong evidence of the heterogeneous nucleation of $\alpha\text{-Al}$ on Al_3Ti particles, though under a condition of large excess of titanium in the aluminum melt. However, deep etching of Al-Ti-B master alloys revealed that the large Al_3Ti particles are, in fact, duplex particles consisting Al_3Ti and TiB_2 , as shown in Fig. 3.^[8,9,19,21,22] Moreover, these large duplex particles are not simply agglomerates of the different particles but there are crystal orientation relationships between these two phases, an evidence of epitaxial growth of one on another. And Al_3Ti in each of the duplex particles is polycrystalline of smaller Al_3Ti particles. These findings, in combination with other findings, have led to a new grain refinement mechanism, which will be discussed in a grain refinement mechanism section later.^[8,19,22] It can, therefore, be elucidated from the observations that Al_3Ti grows on TiB_2 particles and agglomerates/grows into large duplex $\text{Al}_3\text{Ti-TiB}_2$ particles. Meanwhile, a large number of smaller TiB_2 particles are also observed along the $\alpha\text{-Al}$ grain boundaries

Fig. 3 Deep-etched Al-Ti-B master alloy showing duplex $\text{Al}_3\text{Ti-TiB}_2$ particles

in association with impurities, such as Fe and Si, in Fig. 2. A question is therefore raised why TiB_2 particles that were formed at the same time in the same process behave differently, i.e., either within duplex particles in α -Al grain centers or along α -Al grain boundaries. The different distribution of TiB_2 particles may also have different effects on nucleating α -Al grains in grain refinement. To answer the question, the formation and growth of Al_3Ti and TiB_2 particles in the production of Al-Ti-B master alloys will be discussed in the following two sections.

Formation of Al_3Ti Particles in Al-Ti-B and Al-Ti Master Alloys

Three types of Al_3Ti particles have been observed in Al-Ti master alloys, blocky, flaky, and petal-like, as a result of different thermal histories. Blocky Al_3Ti particles need a short contact time to reach an optimum grain refinement, while flaky Al_3Ti particles require a longer contact time.^[29] Al_3Ti has a body-centered tetragonal (BCT) crystal structure with a Laue symmetry 4/mmm and lattice parameters $a=0.386$ nm and $c=0.868$ nm. It can be treated as the replacement of Al atoms in a face-centered cubic (FCC) aluminum crystal structure by titanium in certain positions. The formation of Al_3Ti in an aluminum melt is therefore highly related, but not limited, to the crystal structure and the processing history.^[20,30] High temperature and a moderate cooling rate result in the formation of flaky Al_3Ti , high temperature and high cooling rate lead to a petal-like Al_3Ti , and low temperature and high supersaturation form blocky Al_3Ti . Blocky and flaky Al_3Ti particles are commonly observed in commercial Al-5Ti-1B master alloys that have been produced in a temperature range of 750°C–900°C.^[8,9,20,22] The formation of blocky and flaky Al_3Ti is a result of different growth rates along its different crystal directions on different crystal planes.^[30]

The formation of Al_3Ti particles consists of nucleation and growth stages similar to other phase transformations, which requires overcoming an energy barrier for the nucleation of a new phase and then a driving force for the growth of the newly formed phase. The nucleation of Al_3Ti in binary Al-Ti master alloys is driven by a supersaturation of solute Ti in the aluminum melt. After the chemical reduction of titanium from K_2TiF_6 , the concentration of titanium in solution increases to a level higher than the solubility of titanium in aluminum as shown in the Al-Ti phase diagram in Fig. 4.^[7] According to the phase diagram, the solubility of titanium in an aluminum melt is lower than 1 wt% Ti under a processing temperature below 900°C, which is the highest temperature that could be reached in an industrial process. Once saturated, solute Ti will react with aluminum to form Al_3Ti . With a continuous supply of Ti atoms from the reduction of K_2TiF_6 , Al_3Ti grows into larger sizes. The growth of Al_3Ti consumes both solute Ti and smaller Al_3Ti particles, leading to different morphologies of the large Al_3Ti particles.^[30] In the presence

Fig. 4 The aluminum side of an Al-Ti phase diagram^[7]

of stable TiB_2 particles in Al-Ti-B master alloys, Al_3Ti forms on the surface of TiB_2 particles through heterogeneous nucleation at the Al/molten-salt interface, leading to the formation of individual Al_3Ti particles growing on individual TiB_2 cores, called composite $\text{Al}_3\text{Ti-TiB}_2$ particles thereafter to distinguish from duplex $\text{Al}_3\text{Ti-TiB}_2$ particles. Due to the high population of TiB_2 particles, which is shown in the microstructure of Al-5Ti-1B master alloys, a large number of $\text{Al}_3\text{Ti-TiB}_2$ composite particles form at the Al/molten-salt interface leading to agglomeration and the formation of duplex $\text{Al}_3\text{Ti-TiB}_2$ particles. The composite particles grow in the same manner as the growth of Al_3Ti in an Al-Ti master alloy. The consumption of smaller Al_3Ti particles through surface diffusion in the agglomerates exposes some of the TiB_2 cores and results in the formation of duplex $\text{Al}_3\text{Ti-TiB}_2$ particles that are reported in the literature.^[8,9,20,22]

Formation of Diboride (TiB_2 - AlB_2) Particles in Al-Ti-B Master Alloys

Diboride particles, TiB_2 and AlB_2 , in Al-Ti-B master alloys are in shapes of hexagonal disks. Transmission electron microscopic analysis revealed that the diboride particles are made up of clusters of submicrometer diborides, which are in the form of hexagonal crystals bounded by $\{10\bar{1}0\}$ prism planes.^[20,31] The so-called TiB_2 particles are, in fact, mixtures of TiB_2 and AlB_2 in a variable ratio. It raises a question about the stability of the two diboride phases. The initial composition of the $(\text{Ti,Al})\text{B}_2$ phase is determined by the fabrication history, especially the order of titanium and boron additions. After a long period of holding in the liquid state, a transformation from $(\text{Ti,Al})\text{B}_2$ toward TiB_2 was observed, which stops before pure TiB_2 is reached.^[9,20] However, this may only happen when there is a high concentration of solute Ti to react with AlB_2 .

The formation of TiB_2 is rather straightforward by the reaction of titanium and boron that have been reduced from K_2TiF_6 and KBF_4 at the Al/molten-salt interface due to the low solubility of TiB_2 in an aluminum melt. In the production of Al-5Ti-1B master alloys, for example, the TiB_2 is formed in an aluminum melt containing about 0.5–1 wt% Ti in solution. The TiB_2 is, therefore, stable thermodynamically due to the high concentration of solute Ti. However, there is always an AlB_2 phase being found in the diboride particles by X-ray diffractions (XRD).^[9,22] Diborides of Ti, Al, V, and Zr have the same hexagonal crystal structure with small differences in their crystal constants.^[22] Therefore, the formation of a solid solution is more than likely a mixture of separate single phases from a thermodynamic point of view, which is also confirmed by XRD analyses that the diboride peaks shifted from one single phase to another gradually when Ti/Zr ratio varied gradually in the diboride particles.^[22] The phase transformation from AlB_2 to a more stable VB_2 has been proven true in the industrial practice of removing solute V by adding AlB_2 in the form of Al-B master alloys.^[32] The transformation of both solid solutions of $(\text{Ti,Al})\text{B}_2$ and a mixture of TiB_2 and AlB_2 to pure TiB_2 in Al-Ti-B master alloys, which have a high concentration of titanium, is therefore predictable, i.e., AlB_2 transforms to TiB_2 , though it appears a very slow process. And it is more likely that an equilibrium exists in the transformation of $(\text{Ti,Al})\text{B}_2$ solid solution to TiB_2 .

The solution product of TiB_2 in an aluminum melt was reported as small as 1×10^{-11} at 973 K, which means virtually insoluble.^[33] The formation of TiB_2 at the Al/molten-salt interface is, therefore, immediate after the reduction of titanium and boron from their fluoride salts. Once formed and moved away from the Al/molten-salt interface, the growth of the TiB_2 particles becomes difficult as there is a lack of boron in solution for the formation of new boride layers on the surface of the TiB_2 particles. Meanwhile, there is a large amount of excess titanium in solution, which forms Al_3Ti phase once the concentration passes the liquidus in an Al-Ti phase diagram either due to the buildup of titanium from salt reduction or supersaturation from cooling. In the presence of TiB_2 particles, Al_3Ti grows on the surface of the TiB_2 particles through heterogeneous nucleation rather than homogeneous nucleation from the supersaturated Al-Ti melt. As a result, numerous composite Al_3Ti - TiB_2 particles form with a hard TiB_2 core covered by Al_3Ti on the surface. These composite particles then agglomerate into clusters, where smaller ones are consumed by the growth of larger Al_3Ti particles. Eventually, duplex Al_3Ti - TiB_2 particles form in Al-Ti-B master alloys as shown in Fig. 3. During the growth of Al_3Ti , TiB_2 particles may be either engulfed or rejected by the growth of the duplex particles. TiB_2 particles that have been rejected by the duplex particles generally show a weaker ability in nucleating Al_3Ti in comparison with those being engulfed. The engulfed TiB_2 particles are therefore claimed more

active than the TiB_2 particles at the α -Al grain boundaries in the as-cast Al-Ti-B master alloys attributed to their high potency in nucleating Al_3Ti .

Fabrication of Al-Ti-B Master Alloys

As stated earlier, Al-Ti-B master alloys are produced by chemical reactions of molten aluminum and mixtures of K_2TiF_6 and KBF_4 salts. The chemical reactions take place inside a graphite or graphite-bonded silicon carbide crucible that is heated up to a setting temperature, which varies generally between 750°C and 900°C depending on different manufacturers. The chemical reactions are exothermic resulting in an increase in temperature. The release of a large amount of heat also makes temperature control difficult and maintaining isothermal reaction impossible. This makes size control for Al_3Ti and TiB_2 , particularly Al_3Ti , particles difficult because the growth of the particles is sensitive to temperature.^[9,30] At a temperature higher than 750°C, the product salts, particularly KAlF_4 , evaporate as smoke, which must be collected to protect the environment. The heating can be made by using electrical resistance furnaces or induction furnaces. The latter is more common for uniform temperature throughout of the melt due to the induction effects. There is not a detailed industrial procedure available in open literature. However, a general procedure is mixing the salts first, then adding the salt mixture into a crucible that contains an aluminum melt at a setting temperature. The salt mixture can be added as drosses or continuously in a controlled rate. The aluminum melt is stirred during the addition of salts by either/both mechanical stirrer or/and induction field. After the completion of chemical reactions between the aluminum melt and the fluoride salts and subsequently the formation of Al_3Ti and TiB_2 particles, the salt products on top of the aluminum melt are poured off. The Al-Ti-B master alloys are degassed and then casted into ingots using permanent molds or into bars followed by rolling or extrusion into rods.

The cast ingots are directly added into an aluminum melt in a holding furnace before casting for grain refinement due to the long contact time of the master alloy ingots. And the rods are fed into an aluminum stream in a controlled manner by a specially designed feeding machine in continuous casting, e.g., the DC casting of pure aluminum, because of their short contact time. In the rolling or extrusion of Al-Ti-B master alloys, duplex Al_3Ti - TiB_2 particles are broken up into smaller pieces, which show improved grain refinement capabilities. The reason is not clear for the better performance of the broken Al_3Ti particles. But one thing is for certain: that the broken Al_3Ti particles change the dissolution of the Al_3Ti and the settling of TiB_2 particles in an aluminum melt. Different forms of Al-5Ti-1B master alloys that are available in the market are shown in Fig. 5, where the diameter of the rods is 3/8 in.

Fig. 5 Different forms of Al-5Ti-1B master alloys in the market

GRAIN REFINEMENT USING MASTER ALLOYS

The grain refinement of aluminum consists of two subsequent stages, to nucleate α -Al grains and to restrict the growth of the α -Al grains. The former is achieved through the addition of large numbers of inoculants or particles as heterogeneous nucleation sites for α -Al grains. Then the growth of the α -Al grains must be restricted through constitutional cooling to avoid the formation of harmful columnar or twined columnar α -Al grains. For the nucleation of α -Al grains in solidification, two mechanisms may be in effect theoretically, homogeneous nucleation and heterogeneous nucleation. The energy barrier for homogeneous nucleation is much higher than that of heterogeneous nucleation.^[34] Also, it is not practical to do grain refinement by homogeneous nucleation of α -Al grains because there are always potential heterogeneous nucleation sites, such as intermetallic phases and mold surfaces. To achieve a desirable grain refinement, heterogeneous nucleation must take place at a temperature higher than the nucleation of α -Al grains on other substrates, such as the mold walls. Al-Ti-B master alloys, therefore, become the ideal candidate grain refiners attributed to the special properties of TiB_2 and Al_3Ti , which coexist in the Al-Ti-B master alloys. The TiB_2 particles are generally in smaller sizes of a few micrometers and are fully wetted by liquid aluminum, which makes the dispersion of TiB_2 in an aluminum melt more uniform than other inoculants. From an energy point of view, TiB_2 particles are ideal heterogeneous nucleation sites for α -Al grains due to a zero degree of wetting angle by liquid aluminum under the production conditions, i.e., the existence of molten salts.^[35] However, the addition of TiB_2 particles or titanium and boron in the stoichiometric ratio of TiB_2 does not lead to grain refinement at all, i.e.,

TiB_2 itself does not nucleate α -Al grains strong enough for grain refinement. In the meantime, Al_3Ti particles are also added into an aluminum melt when Al-Ti-B master alloys are used. Al_3Ti dissolves into the aluminum melt forming high concentration of solute Ti in the aluminum melt. Upon cooling, the solubility of titanium in the aluminum melt decreases following the liquidus of the Al-Ti phase diagram in Fig. 4. Al_3Ti nucleates on the surface of TiB_2 particles in an aluminum melt at temperatures higher than the melting point of aluminum.^[36] The Al_3Ti then nucleates α -Al grains in a similar way that Al-Ti master alloys do in grain refinement. However, due to the presence of more stable TiB_2 particles, the formation of Al_3Ti on the surface of TiB_2 becomes easier than the formation of Al_3Ti in an Al-Ti melt when Al-Ti master alloys are used for grain refinement. One adverse effect of TiB_2 nucleating Al_3Ti is that once stable Al_3Ti forms on the surface of TiB_2 , the Al_3Ti grows rapidly to form duplex $\text{Al}_3\text{Ti-TiB}_2$ particles. To avoid the formation of duplex $\text{Al}_3\text{Ti-TiB}_2$ particles and the loss of grain refinement efficiency, the formation of Al_3Ti on TiB_2 must be controlled to an optimal level, which will be discussed later.

The grain refinement of Al-Ti master alloys is explained through a peritectic reaction of Al_3Ti and liquid aluminum, as shown in reaction 4, derived from the Al-Ti binary phase diagram. The Al_3Ti particles are brought into the aluminum melt as Al-Ti master alloys, which dissolve into molten aluminum and release Al_3Ti particles into the melt. Al_3Ti particles dissolve into molten aluminum when the concentration of titanium is less than 0.15 wt% at 665°C as can be seen from the Al-Ti phase diagram. The nucleation of α -Al on Al_3Ti is also favored from a crystallographic point of view as the BCT crystal structure of Al_3Ti is simply the combination of two FCC Al units with some

aluminum atoms being replaced by titanium atoms in certain positions. An epitaxial growth of FCC aluminum on the surface of BCT Al_3Ti happens naturally in solidification. The solidification process is also accompanied by the diffusion of titanium atoms into the FCC aluminum crystal lattice forming a solid solution of Ti in $\alpha\text{-Al}$. This is one of the reasons that there is still a dispute about the nucleation mechanisms of grain refinement of aluminum by Al-Ti and Al-Ti-B master alloys as the observation of an Al_3Ti layer on TiB_2 or Al_3Ti particles in industrial casting products is impossible.

In the presence of more stable TiB_2 particles, Al_3Ti forms on TiB_2 before the nucleation of $\alpha\text{-Al}$ grains through a heterogeneous nucleation process. The grain refinement of Al-Ti-B master alloys is achieved through a heterogeneous nucleation of $\alpha\text{-Al}$ grains on the TiB_2 particles that are covered by a Al_3Ti layer, which is also reported as a Ti-rich layer.^[16] Specially designed experiments demonstrated that the Ti-rich layer is Al_3Ti when exogenous TiB_2 particles are introduced into the aluminum melt.^[17] The Al_3Ti layer modifies the surface condition of TiB_2 particles and nucleates $\alpha\text{-Al}$ grains during solidification. This is supported by the observed orientation relationships between these particles and the $\alpha\text{-Al}$ matrix.^[23] The addition of Al-Ti-B master alloys introduces large quantity of TiB_2 particles, among which only a small fraction participates in nucleating $\alpha\text{-Al}$ grains effectively.^[9]

In summary, the following major theories for grain refinement of aluminum by Al-Ti-B master alloys have been proposed:

1. Boride/carbide theory^[4,11]

The theory was developed based on two factors that boride and carbide particles are stable in an aluminum melt and TiB_2 particles were observed in the $\alpha\text{-Al}$ grain centers with $\alpha\text{-Al}$ dendrites grew on the particles.^[17,20,37–39] Carbide particles are mentioned together with boride due to the production of Al-Ti-B master alloys, which uses graphite or SiC-graphite crucibles. The formation of TiC is, therefore, unavoidable despite no detailed analyses were done to prove the formation of TiC in the production of Al-Ti-B master alloys. It is proposed that $\alpha\text{-Al}$ nucleates on the boride/carbide particles through epitaxial growth. Orientation relationships between TiB_2 particles and $\alpha\text{-Al}$ matrix were identified as the closely packed directions on the hexagonal closely packed TiB_2 {0001} and FCC Al {111} planes parallel to each other.^[23] However, a big challenge of this theory is that adding TiB_2 or AlB_2 particles solely does not grain refine aluminum at all, and excess amount of titanium than the stoichiometry of TiB_2 is necessary

for an effective grain refinement. Therefore, a direct nucleation of $\alpha\text{-Al}$ on boride or carbide particles leading to grain refinement in industrial practices is not true.

2. Peritectic theory^[7,40]

It is based on the existence of a peritectic reaction in an Al-Ti phase diagram, where the solubility of titanium in an aluminum melt reduces rapidly when temperature drops leading to the precipitation of Al_3Ti . There is much evidence that Al_3Ti in $\alpha\text{-Al}$ grain centers and TiB_2 particles exist at the $\alpha\text{-Al}$ grain boundaries after solidification of an aluminum melt, particularly in Al-Ti-B master alloys.^[19,22,31] As stated before, the BCT crystal structure of Al_3Ti is merely a repeat of the FCC crystal structure of $\alpha\text{-Al}$ with certain replacement of aluminum atoms by titanium. The crystal discrepancy between Al_3Ti and $\alpha\text{-Al}$ grain is small.^[20,23] The nucleation of $\alpha\text{-Al}$ from Al_3Ti is therefore favored. Furthermore, Al-Ti master alloys have been used industrially for grain refinement of aluminum. There is not a single doubt about Al_3Ti nucleating $\alpha\text{-Al}$ grains. However, Al_3Ti can grow into large sizes and different morphologies easily depending on processing histories and alloy compositions.^[30] And more importantly, Al_3Ti is not stable in an aluminum melt under an industrial casting condition, i.e., titanium is less than 0.15 wt%. The formation of stable Al_3Ti in this theory is questionable.

3. Duplex nucleation theory^[17,23]

In this theory, Al_3Ti forms on the surface of TiB_2 particles and then nucleates $\alpha\text{-Al}$ grains, which is a combination of the boride/carbide theory and the peritectic theory. The observation of Al_3Ti on the surface of TiB_2 particles in $\alpha\text{-Al}$ grain centers supports this theory very well when titanium is largely in excess the stoichiometry of TiB_2 , such as Al-5Ti-1B master alloys. However, it still could not answer the question of how stable Al_3Ti could form on TiB_2 when the titanium concentration is less than 0.15 wt%. A continuous effort has been made to prove the existence of stable Al_3Ti in an aluminum melt either as a layer at the $\text{TiB}_2/\alpha\text{-Al}$ interface or isolated Al_3Ti particles. The existence of a Ti-rich layer with a similar crystal structure to that of Al_3Ti and a 2-D single atomic Al_3Ti layer at the $\text{TiB}_2/\alpha\text{-Al}$ interface was reported.^[14,37,41] To support the existence of Al_3Ti in an aluminum melt, a proposition was also made that TiB_2 forms a shell around Al_3Ti and slows down the dissolution of Al_3Ti eventually keeps a cell of liquid approximately peritectic composition inside a boride cell to be the nucleation site for $\alpha\text{-Al}$ grains.^[42,43] However, a fundamental question about the stability of Al_3Ti in an aluminum melt with less than 0.15 wt% Ti is still not answered, which

makes the theory not suitable for the explanation of aluminum grain refinement.

4. Dynamic nucleation theory^[8,19,22,36,44]

The theory claims that TiB_2 particles nucleate a dynamic Al_3Ti layer and then nucleate $\alpha\text{-Al}$ grains. Only when the Al_3Ti layer is in a transient state, can grain refinement be realized. Otherwise, some of the Al_3Ti particles will grow and consume other Al_3Ti on the majority of TiB_2 particles leading to the formation of duplex $\text{Al}_3\text{Ti-TiB}_2$ particles. The duplex $\text{TiB}_2\text{-Al}_3\text{Ti}$ particles have a much higher potential in nucleating $\alpha\text{-Al}$ grains leading to the formation of a microstructure similar to that of Al-Ti-B master alloys, as shown in Fig. 2. To achieve a grain refinement, Al_3Ti must coat the major population of TiB_2 particles, which can only be maintained by a dynamic layer of Al_3Ti . And the industrial grain refinement conditions meet the requirement of forming a dynamic Al_3Ti layer on the surface of TiB_2 particles.^[8,19,22,36,44] This latest theory is proposed based on the dissolution of TiB_2 in an aluminum smelter, the impurity level of titanium in commercial purity aluminum alloys, the formation of $(\text{Ti,Al})\text{B}_2$ solid solutions, and crystal orientation relationships of TiB_2 and Al_3Ti .

In summary, the boride/carbide theory claims that TiB_2 particles nucleate $\alpha\text{-Al}$ grains directly for grain refinement when Al-Ti-B master alloys are added for grain refinement. It has been proven primitive due to the lack of analytical means in the mid of 20th century. The peritectic nucleation theory states that $\alpha\text{-Al}$ nucleates on the surface of Al_3Ti . However, Al_3Ti is not a stable phase under industrial grain refinement conditions. The duplex theory requires the formation of stable Al_3Ti on TiB_2 to nucleate $\alpha\text{-Al}$ grains. It faces the same difficulties that the peritectic theory faces, which is the stability of Al_3Ti in grain refinement practice. The titanium concentration in an aluminum melt, both from Al-Ti-B master alloys and impurities from smelters, and the solubility of TiB_2 have never been taken into considerations, until the dynamic nucleation theory was proposed. This theory is not controversial to any of the other proposed theories, but moving one step forward by revealing the transient nature of the Al_3Ti layer for nucleating $\alpha\text{-Al}$ grains.

After nucleation, the growth of $\alpha\text{-Al}$ grains is governed by a diffusion-controlled process of a hypoperitectic Al-Ti melt. The growth is inversely related to the constitutional supercooling parameter, $mC_o(k-1)$, where m is the slope of the liquidus of the Al-Ti phase diagram, C_o is the titanium solute concentration, k is the equilibrium partitioning coefficient (C_s/C_l , C_s and C_l are the solute concentrations of the solid and liquid, respectively).^[1,10] The values of growth restriction factors for Ti, Zr, and V at the peritectic composition are 31, 5, and 0.5, respectively. Titanium is therefore most effective among these three elements for grain refinement purposes.

Grain Refinement Practice

A typical aluminum grain refinement curve consists of two portions, a contact time to reach an optimum grain refinement and a fading stage after the optimum contact time is reached, as shown in Fig. 6.^[5] To achieve an optimum grain refinement, i.e., the smallest casting grain size, a holding time is required and is called contact time. The contact time is for achieving a homogeneous dispersion of TiB_2 particles and the dissolution of Al_3Ti into the aluminum melt. It is related to the microstructures of the master alloys, particularly the sizes and shapes of duplex $\text{Al}_3\text{Ti-TiB}_2$ particles. As an example, large blocky Al_3Ti requires a longer contact time than that for smaller flaky Al_3Ti particles. After the addition of Al-Ti-B master alloys, duplex $\text{Al}_3\text{Ti-TiB}_2$ particles dissolve forming solute Ti and releasing TiB_2 particles into the aluminum melt. TiB_2 particles first disperse in the aluminum melt, then settle down to the bottom of the furnace. Once an optimum contact time is reached, the settlement of TiB_2 particles takes control and fading starts. The optimum grain refinement can be regained by stirring the aluminum melt. The settling of TiB_2 particles is affected by several factors, including agglomeration of the TiB_2 particles and alloying elements in the aluminum melt. An acceptance level of the grain size was given as $220\text{ }\mu\text{m}$.^[5] However, an acceptable grain size is quite flexible depending on the processing and application of the castings.

Master alloys can be introduced into an aluminum melt at different processing stages according to the type of master alloys and the composition of the aluminum melt because mainly of their different contact times and fading characteristics. The master alloys can also be added into an aluminum melt as either casting waffles or rolling/extrusion rods. The waffles are added into the casting furnace because of its longer contact time compared to the rods, which are normally added before a degasser. Figure 7 is a schematic

Fig. 6 A typical grain refinement curve^[5]

drawing of processing of primary aluminum from electrolysis to casting, in which master alloys are added in a form of rod through a feeder, which can be bought from one of the major master alloy producers. Clusters of TiB_2 particles are filtered out before casting. Only in very few cases are the master alloys added after the in-line filter, because the addition of master alloys inevitably introduces a large quantity of TiB_2 particles, which may form harmful agglomerations. The TiB_2 agglomerations must be removed before casting by filtration.

Two important phenomena of the grain refinement of aluminum by Al-Ti-B master alloys are fading and poisoning. Fading may be a direct result of settling of TiB_2 particles because stirring can regain grain refinement efficiency. As shown in Fig. 7, fading happens after the melt is held for a long time period from the addition of Al-Ti-B master alloys to casting. Poisoning is an effect of the interaction of the inoculants with certain alloying elements, such as Zr and Si, leading to the loss of grain refinement of the master alloys. It is generally believed that the alloying elements replace some of the titanium and segregate to the surface of the TiB_2 particles leading to a high crystal mismatch of the coating on TiB_2 with $\alpha\text{-Al}$ in solidification. Zr also reacts with TiB_2 causing the growth of $(\text{Ti,Zr})\text{B}_2$ particles along the $\langle 0001 \rangle$ crystal direction and reduces the exposure of the basal planes, which are the planes responsible for the epitaxial growth of $\alpha\text{-Al}$.^[22]

TiB_2 particles have been considered nuisance in castings for subsequent processing, especially for rolling and extrusion. As inclusions, the particles may cause a reduction in formability locally acting as stress raisers. In some cases, such as can body sheets and foils, the particles may be larger than the section size and causing through holes. Al-Ti-B master alloys with higher Ti/B ratios than 5/1, i.e., less TiB_2 particles than that of Al-5Ti-1B, are, therefore, used in these cases. The harmful effects of TiB_2 particles become detrimental when agglomeration happens. The

defects that may be caused by inclusions are summarized as follows:^[45]

1. Score on extrusion dies, and therefore die lines on extrusion surface.
2. Flange split and pinholes in can body.
3. Pinholes in foils.
4. Machining problem and bad surface finish.
5. Fracture in service.

Information about the role of TiB_2 particles in rolling and extrusion is very limited due to its industrial sensitivity. Detailed investigation in Alcan, however, demonstrated its beneficial effects on extrusion and heat treatment. One thing that should be noted is that the results are the co-effects of grain refinement and TiB_2 addition. Because TiB_2 particles are introduced by the addition of Al-Ti-B grain refiners, the TiB_2 particle size is small ($\sim 3\text{ }\mu\text{m}$). And the processing ability of the alloys is improved by grain refinement.

Despite Al-Ti-B master alloys are effective in aluminum grain refinement, hard TiB_2 particles are brought into the castings, leading to difficulties in follow-on processing, particularly when agglomeration of the TiB_2 particles forms. The cleanliness of the aluminum melt, therefore, must be closely monitored. LiMCA, PoDFA, and several TAC and filtration techniques make in-line inclusion monitoring and removal possible.^[46,47] The inclusion removal techniques consist of settling, floatation, filtration.^[45]

Grain Refinement Tests

The grain refinement performance of a master alloy must be evaluated to assure its reliability. The addition of master alloys in DC casting is generally made in a range of 0.5–2 kg/ton of aluminum melt. To evaluate a master alloy, the master alloy is stirred into an aluminum melt in a crucible and held for a certain time period, about 15 min, inside a holding furnace. Then a ladle is used to take melt out of the crucible in a certain position before pouring into a mold. Depending on manufacturers and end users, different molds are used. Ring test and golf-tee molds are used by a master alloy manufacturer; meanwhile, end users use their own testing methods.^[1,9] There is also a standard test procedure for aluminum alloy grain refiners by the Aluminum Association.^[48]

The KBI ring test is the simplest and convenient to use. It casts aluminum melt into a ring of 2.5 in. diameter and 1.5 in. height on top of a piece of refractory brick at 720°C . After solidification, the aluminum block is etched on the bottom surface by using Keller's etchant, which is an aqueous solution of nitric acid, hydrochloric acid, and hydrofluoric acid in a ratio of 95:2.5:1.5:1 by volume. The grain size is then analyzed under an optical microscope according to a linear intercept method. Photos of test samples without and with the addition of Al-5Ti-1B master alloys are shown

Fig. 7 Schematic processing of primary aluminum production

in Fig. 8a and b, respectively. The grain refinement effects are quite obvious from the unpolished samples. Other methods require cutting the casting samples and then polishing before etching, which are generally not suitable for quick on-site evaluation by the production furnaces.

AL-TI-C MASTER ALLOYS

Al-Ti-C master alloys are another kind of popular grain refiners in addition to Al-Ti-B master for grain refinement of aluminum alloys particularly that are poisonous to the latter.^[24–27,49–56] There are also other benefits when Al-Ti-C master alloys are used in comparison with Al-Ti-B master alloys, such as extended filter life in continuous casting, less hard and coarse particles in products, and therefore less problems in rolling and extrusion.^[24,49]

Similar to the microstructure of Al-Ti-B master alloys, the microstructure of Al-Ti-C master alloys contains large size Al_3Ti and smaller TiC particles.^[56] Al_3Ti particles are in the aluminum grain centers and TiC particles in size of a few micrometers are located along the aluminum grain boundaries. Large Al_3Ti particles are compounded particles of Al_3Ti -TiC with the smaller TiC particles forming on the surface of large Al_3Ti particles. TiC particles are in a blocky shape, which is different from the hexagonal disks of TiB_2 particles in Al-Ti-B master alloys.^[52] This microstructure is a direct result of the production process of the Al-Ti-C master alloys, which involves reactions of Al-Ti alloys with graphite, K_2TiF_6 and graphite with aluminum melt, or elemental titanium and graphite in an aluminum melt at high temperatures.

Al-Ti-C master alloys are normally supplied as rolling bars of a 3/8-in. diameter due to the short contact time of the master alloys and the instability of TiC in an aluminum melt. An SEM image of a commercial Al-3 wt% Ti–0.15 wt% C bar is shown in Fig. 9, where large particles are compounded Al_3Ti -TiC particles and the small ones in strings are TiC particles. Details of the particles are shown

Fig. 9 SEM image of a commercial Al-3 wt% Ti–0.15 wt% C bar

after deep etch in Fig. 10, where (a) shows clusters of small TiC particles and (b) is a large Al_3Ti particle with small TiC particles on its surface. Therefore, there is not a significant difference between the microstructures of Al-Ti-B and Al-Ti-C master alloys.

TiC particles are not thermodynamically stable in an aluminum melt though stable in Al-Ti-C master alloys.^[27] Reactions 5 and 6 of TiC with an aluminum melt may exist to form a surface coating of Al_4C_3 and Ti_3AlC , which poisoning TiC in nucleate α -Al grains.^[49] Therefore, Al-Ti-C master alloys have a short contact time and fading happens irreversibly. The growth of TiC particles is also sensitive to the processing conditions, especially processing temperature, leading to different particle sizes in master alloys from different suppliers. Large size TiC particles result in a high noise level in online ultrasonic inclusion detection in rolling.

Theories about the grain refinement of Al-Ti-C master alloys are similar to those proposed for Al-Ti-B master alloys, i.e., heterogeneous nucleation from small TiC particles which has a small crystal registry with α -Al grains and the constitutional cooling of solute titanium from the dissolution of Al_3Ti particles.

CONCLUSION

Aluminum grain refinement through inoculation is a routine industrial practice to produce equiaxed casting α -Al grains. TiB_2 and TiC particles are the two most popular inoculants brought in by the addition of Al-Ti-B and

Fig. 8 Grain refinement by KBI ring test method using an Al-5Ti-1B master alloy, (a) pure aluminum without the addition of a master alloy and (b) with the addition of 0.01 wt% Ti and 0.002 wt% B

Fig. 10 SEM images of deep-etched commercial Al-3Ti-0.15C master alloy, (a) shows clusters of TiC particles and (b) is a big Al_3Ti particle with small TiC on its surface

Al-Ti-C master alloys, respectively. An amount of excess titanium than the stoichiometry of TiB_2 and TiC in the form of Al_3Ti particles in the master alloys is necessary for the heterogeneous nucleation of $\alpha\text{-Al}$ on TiB_2 and TiC particles and to restrict the growth of the $\alpha\text{-Al}$ grains through a constitutional cooling effect. As shown by the microstructures of the master alloys, excess titanium causes growth of duplex $\text{Al}_3\text{Ti-TiB}_2$ particles leading to a lot of the TiB_2 and TiC particles being pushed into the $\alpha\text{-Al}$ grain boundaries, i.e., losing their ability in nucleating $\alpha\text{-Al}$ grains. The formation of a stable Al_3Ti layer on the surface of TiB_2 to nucleate $\alpha\text{-Al}$ grains is therefore not realistic. The formation of a dynamic Al_3Ti layer, which promotes the nucleation of $\alpha\text{-Al}$ grains and at the same time avoids agglomeration and growth of the Al_3Ti particles, is more reasonable. The amount of excess titanium in a master alloy is not critical as long as it is sufficient to form a dynamic layer of Al_3Ti and not to form duplex $\text{Al}_3\text{Ti-TiB}_2$ particles in an aluminum melt for grain refinement.

To develop more effective grain refinement master alloys for aluminum casting, smaller particles of TiB_2 and TiC are recommended. Smaller TiB_2 and TiC particles not only offer more heterogeneous nucleation sites, through Al_3Ti though, for $\alpha\text{-Al}$ grains, but also lead to less harmful inclusions in the final products, particularly rolling plates and foils that are sensitive to inclusions. One way of doing so is to apply low processing temperature and strong agitation to the Al/molten-salt interface to restrict the growth of the TiB_2 and TiC particles.

Melt Quality Assessment

Derya Dispinar

Metallurgical and Materials Engineering, Istanbul University-Cerrahpasa, Avcilar, Istanbul, 34320, Turkey

Abstract

It is well known that the reaction of liquid aluminum with the moisture in the environment results in two products: aluminum oxide and hydrogen gas that dissolves in aluminum. Both of these products are considered to be detrimental to the properties of aluminum alloys. Therefore, test equipment has been developed to check the levels of these defects in the melt. Many of these involve expensive and consumable tools. In addition, an experienced personnel may be required to interpret the results. Nonetheless, aluminum oxide is harmless as long as it remains on the surface. The problem begins when this oxide is entrained into the liquid aluminum such as turbulence during transfer or mold filling in a non-optimized design. This can only happen by folding of the oxide. During this action, rough surface of the oxides comes in contact to form no bonds. These defects are known as bifilms that have certain characteristics. First, they act as cracks in the cast parts since they are oxides. It is important to note that aluminum oxide has thin amorphous oxide (known as young oxides) and thick crystalline oxide ($\gamma\text{-Al}_2\text{O}_3$) that may be formed in a casting operation. Second, almost zero force is required to open these bifilms due to the unbonded folded oxide skins. Thus, these defects can easily form porosity by unravelling during solidification shrinkage. On the other hand, the formation of porosity by hydrogen is practically impossible. Theoretically, hydrogen has high solubility in the liquid but it has significantly low solubility in solid aluminum. Thus, it is suspected that hydrogen is rejected from the solidification front to form hydrogen gas and porosity. However, the hydrogen atom has the smallest atomic radii and high diffusibility. Therefore, segregation of hydrogen in front of the growing solid is difficult. In addition, the energy required for hydrogen atoms to segregate and form hydrogen gas molecule is around 30,000 atm. Under these conditions, porosity formation by hydrogen is not likely to be achieved. Hydrogen probably stays in a supersaturated state or diffuses homogeneously through the cast part. The effect of hydrogen can only be seen when it can diffuse into the unbonded gap between the bifilms to open them up to aid the unravelling of bifilms to form porosity. This phenomenon can be easily detected by a very simple test called reduced pressure test. When a sample is solidified under vacuum, the bifilms start to open up. Since all porosity is formed by bifilms, the cross section of the sample solidified under vacuum can be analyzed by means of image analysis software. The sum of maximum length of pores can be measured as an indication of melt quality. Since bifilms are the most detrimental defects, this value is called “bifilm index” given in millimetres, which makes this test the only test that can quantify aluminum melt quality in such detail including both the effects of bifilms and hydrogen together. Several Al–Si alloys were used at various conditions: degassing with lance, ceramic diffusers, and graphite rotary has been compared. Gravity sand casting, die casting, and low-pressure die casting methods were evaluated. The effect of grain refiners and modifiers was studied. And the evolution of the bifilm index has been presented.

INTRODUCTION

In order to produce high-quality aluminum castings, many methods have been developed and further studies are still undergoing.^[1–17] The focus has mainly been on the removal of hydrogen and impurities from the melt prior to casting. Therefore, one of the most important issues has been the detection of these defects. And most particularly, the quantification has been the greatest challenge.

According to the reaction of liquid aluminum with moisture in the surrounding,

This is a well-accepted reaction as many of the major defects are caused by these phenomena: the oxide formation and hydrogen dissolution.

The simplest quantification has been made for hydrogen detection. According to Sievert's Law, the solubility of

hydrogen in liquid aluminum can be calculated.^[18] Therefore, devices have been produced such that either hydrogen partial pressure is measured or the chemical potential is compared with a known concentration. In one of these tests, hydrogen is solidified under vacuum, and the hydrogen that is released from the melt is collected in a chamber where the partial pressure of hydrogen is measured. In another test, a probe is dipped into the melt, and nitrogen gas is circulated through the melt. After a certain time, the hydrogen concentration in the circulating nitrogen bubbles comes in equilibrium with the melt and thus the hydrogen content can be measured by measuring the partial pressure again. In another test, a probe is dipped into the melt that has a known electrolyte concentration cell, and the difference between the melt hydrogen concentration and the reference is measured.

As can be expected, all of these devices contain some sort of technologically advanced electronic devices and consumables that causes the equipment to be expensive. Nevertheless, there is an alternative method. Hydrogen is the only soluble gas in liquid aluminum. Its solubility is high in liquid but significantly low in solid.^[18] Thus, it has been proposed that since all porosity is formed due to hydrogen, then, by simple solidification of a small quantity under vacuum, enhanced pore formation can be triggered, and a porous sample can be obtained. Regarding the Archimedes Principle, density of this porous sample can be measured and the volume of the pores can be correlated with hydrogen. The analytical approach can be summarized as follows:

$$d = \frac{m}{V}$$

where d is density, m is mass, and V is volume.

$$d = \frac{m_m + m_g}{V_m + V_g}$$

m_m is the mass of metal, m_g is the mass of gas, V_m is the volume of metal, and V_g is the volume of gas. Since the weight of the gas can be neglected, thus,

$$d = \frac{m_m}{V_m + V_g}$$

is obtained. According to this equation, the density of the sample is linearly decreased by the increase in the volume of gas, i.e., porosity. It is important to note that this statement is true as long as all the dissolved hydrogen in the melt is transformed to porosity.

By this approach, there is no need for expensive equipment or consumables. Therefore, Reduced Pressure Test has been practically used in almost every foundry floor.^[19–26]

The decrease in density with the volume of gas can be calculated with regard to the vacuum level selected during the test. According to $P_1V_1 = P_2V_2$, the volume of the gas can be converted to the atmospheric values; for example, if the sample is solidified at 100 mbar, the conversion should be as follows:

$$1000 \cdot V_1 = 100 \cdot V_2$$

$$V_2 = 10 \cdot V_1$$

Thus, it can be seen that the volume of the pores solidified under 100 mbar is 10 times higher than the volume it should correspond at 1000 mbar (atmospheric conditions). Therefore, a simple graph can be plotted with hydrogen content and density of the sample at various vacuum levels. As seen in Fig. 1, the relationship is linear, and the decrease in density is increased with an increased vacuum level.

From this plot, the hydrogen content of the melt can be measured from the density of the samples. A parallel line is drawn from the measured density of the sample. At the cross section of the density with the pressure level used in the test,

Fig. 1 Theoretical density–hydrogen relationship at various vacuum levels

a vertical line can be drawn, and the corresponding hydrogen value is recorded as the hydrogen content of the melt.

Although it looks like a pretty straightforward test, there are many issues that need to be considered. One of them is the selection of proper mold material that will be used in the test. Typically, steel cups are used. Occasionally, these molds are preheated prior to test, however when the mold material is selected as a high thermal conductive material, the solidification rate is increased and thus it is difficult to measure the released hydrogen. Therefore, sand molds (Fig. 2) can be used to remedy this issue.^[27,28]

Hundreds of tests were carried out at various conditions for A319, A380, and A356 types of alloys, and all three of the major hydrogen measurement methods were used to measure the hydrogen content of the melt, and the results were aimed to be correlated with the density of samples.^[27,28] These results are given in Figs. 3–7 for 1000, 200, 100, 50, and 10 mbars.

Fig. 2 Dimension of the sand mold used in RPT

As can be seen from these figures, it is almost impossible to correlate the density of the samples solidified under vacuum with the hydrogen levels. Weibull statistics were also used to check the reproducibility of the test results and are given in Fig. 8, the scatter of the results increase (i.e., Weibull modulus decrease) with the increased vacuum levels.

Similarly, average pore area and pore% were also plotted (Figs. 9 and 10), and it can be clearly seen that there was no correlation with pores and hydrogen content of the melt. Velasco^[29] carried out a similar work with RPT and concluded that the density of the samples was not directly related to the hydrogen content of the melt.

When the theoretical lines in Figs. 3–7 are considered, any experimental data that is above this line (i.e., higher density) can be easily explained by stating that “maybe, not all the hydrogen is consumed as pores.” However, what is interesting is the experimental values that are below the theoretical lines. This indicates another source of gas rather than hydrogen. Actually, both of these phenomena (data above and below the theoretical line) and the absence of relationship between hydrogen and density of the samples can be easily explained by the presence of bifilms^[30] (Fig. 11).

Bifilms are known to be the most detrimental defects in casting processes.^[30–50] Their basic characteristic is based on the folding of the oxide skin to form a non-bonded double oxide layer where air gap is present (Fig. 11). Thus, when a melt is turbulently transferred and bifilms are formed, the cast part would already contain a readily present “pore” and the oxide as the inclusion. Therefore, many properties of such a cast part would deteriorate. When considering the behavior of bifilms in the reduced pressure test, the applied vacuum would help bifilms to open up (as in Campbell’s words “unravelling”^[32]) since there is no bond between the folded oxide skins. Going back to Figs. 3–7 and the density values above and below the theoretical lines, it can easily be concluded that all is related with the presence of bifilms.

Fig. 9 Average pore area on the cross section of RPT samples and hydrogen content

Fig. 10 Volumetric pore% of RPT samples and hydrogen content

Fig. 11 Surface turbulence; probably the most common mechanism of introducing bifilms into the melt^[30]

If there are bifilms and they can be opened up, then the density of the samples will decrease (the values that are under the theoretical line). If there are no bifilms, then there will be no porosity, and hence the values above the theoretical line.

The analytical resolving of the Fisher's^[51] approach for porosity formation where Gibbs Energy change is used to calculate the critical pore radius' it can be seen that the pressure difference required for hydrogen atoms to be rejected from the solidification front and to segregate and transform to gas phase is around 30,000 atm for homogeneous

nucleation. For a completely wetting situation, this value can only be lowered down to 1,500 atm, which are too high to be reached and practically impossible. It is also interesting to note that hydrogen is the smallest atom, being in the top left corner of periodical table and the highest diffusible element, it cannot be segregated. Even in the solid aluminum, it can diffuse rapidly. Thus, any pore that is observed in the aluminum castings needs to be formed by a bifilm. Hydrogen can only be a contributor as shown in Fig. 12. Raiszadeh and coworkers^[52–66] have been working on generation of artificial bifilms and their interaction with hydrogen. In addition, the healing of bifilms has been investigated whether the bifilm stays unbonded or can it be transformed to a single film by various alloying element additions and holding times.

All these explanations require some experimental evidences. Therefore, a series of tests were carried out. First test was done at a secondary remelting facility. About 5 tons of melt cast to produce ingots. The filling of the ingots was carried out by a system called "bowl" as shown in Fig. 13.

The melt would hurdle through the laundry and fall from high levels into bowl turbulently, and the bowl would make a rotation action to fill the mold cavity turbulently. The RPT samples collected from these castings are shown in Fig. 14 where large and complex-shaped pores were present.

Fig. 12 Bifilms and porosity formation^[30]

Fig. 13 Ingot filling system: Bowl

Fig. 14 Cross section of RPT samples collected from bowl system (turbulent filling)

The bowl system was then replaced by the wheel system. As seen in Fig. 15, the system transfers the melt in a most convenient way not to disturb the surface oxide (i.e., quiescently).

The cross section of the RPT samples quite remarkably changed compare to the bowl system. As can be seen in Fig. 16, the number of the pores was decreased. In addition, the size of pores was also lowered.

This finding was a straightforward ultimate effect of the bifilms. Therefore, the first approach to the quantification of the RPT test was carried out by measuring the shape factor of the pores on the cross section. Shape factor is $(4\pi \cdot \text{area})$ divided by $(\text{perimeter})^2$. Thus, a shape factor of 1 would indicate perfect circle and 0 would indicate a line. The result is given in Fig. 17. As seen, what was clearly seen by the naked eye was not easily detected by the image analysis software. Although three different software were tested, it was concluded that this approach would not be easy to be interpreted.

Since the pore area observed on the cross section of RPT samples is directly related to the bifilms, the average pore size has to be correlated with the bifilm size, and the number of pores has to be equal to the number of bifilms. Therefore, another quality index was produced from the same set of test results and is shown in Fig. 18. As can be seen, this index was also difficult to interpret.

Fig. 15 Wheel system for producing ingots

Fig. 16 Cross section of RPT samples collected from wheel casting line (quiescent filling)

For simplicity, another index was studied by only using the number of pores. As seen in Fig. 19, this approach was not so feasible again.

Finally, an index was proposed as the sum of maximum length of pores that gave the total oxide length, which was called “bifilm index”.^[28] In this way, the melt quality of aluminum and its alloy can be quantified by a unit given in millimeters for the first time. This index can be acquired by using a sand mold for slower solidification to let the bifilms open (dimension of the mold is given in Fig. 2) at 100mbar vacuum. This is quite practical to be used in foundry floors. For more detailed expenditure, this value can be converted into mm^2 of oxides per mm^3 of aluminum together with the inclusion of number of bifilms (Fig. 20).

Once the bifilm index was proposed, several hundreds of tests and conditions were investigated to compare the bifilm index particularly with pore formation and mechanical properties of several alloys.^[27,28,67–84] In one of these tests, a test matrix was established such that two separate melts of A356 were prepared, where the hydrogen content was gradually increased with Ar–10% H_2 gas and then in the second melt, the hydrogen was first increased and then decreased. The matrix is summarized in Fig. 21.

By selecting a crosswise hydrogen levels, two different bifilm index values were able to be obtained for each hydrogen level of the melt. For example, for 0.1 $\text{cm}^3/100\text{ g Al}$

Fig. 17 Shape factor of pores on the RPT cross section

Fig. 18 Second attempt on quality index including shape factor, average pore area, and number of pores versus density of RPT

Fig. 19 Third attempt on quality index: Number of pores versus density of RPT

Fig. 20 Bifilm index change showing the difference between turbulent and quiescent castings

Fig. 21 Test matrix showing the obtaining of different hydrogen levels

hydrogen level, the bifilm indices were 10 mm and 70 mm for degassed and upgassed melts, respectively. The tensile test results obtained from these melts were analyzed by Weibull methodology and these are given in Figs. 22–24. As seen in Fig. 22a, the casting with the lower bifilm index (10 mm; i.e., higher melt quality) had more reproducible and consistent results with a Weibull modulus of 11.2 for $e\%$ and 49 for ultimate tensile strength (UTS). On the other hand, at the same hydrogen level, the melt with the higher bifilm index (70 mm) had scattered results with a Weibull modulus of 1.13 for $e\%$ and 2.8 for UTS. Similar results were found for the melts where hydrogen content was $0.2 \text{ cm}^3/100 \text{ g Al}$ (Fig. 23). When the hydrogen level was $0.4 \text{ cm}^3/100 \text{ g Al}$, both melts had high bifilm index and very close to each other (90 and 120 mm). And the Weibull modulus of tensile test results was parallel to each other

since they both had the same melt quality (Fig. 24). These findings clearly show that hydrogen content of the melt was not directly related with the mechanical properties. In fact, melt quality, i.e., bifilm index, had predominant impact over tensile properties.

In another test where the effect of bifilms was investigated, a step mold geometry was used as seen in Fig. 25. This mold was designed to be able to be used in both gravity and low-pressure die casting (LPDC) methods. The dimension of the sample that can be produced is 50×120 with a thickness varying from 5 to 30 mm.

Two melts were prepared and the bifilm index of the melts that were used for the gravity and the LPDC castings were 13 and 50 mm for $0.1 \text{ cm}^3/100 \text{ g Al}$ levels, whereas these values were 21 and 56 mm for $0.2 \text{ cm}^3/100 \text{ g Al}$ hydrogen level, respectively. Thus, gravity die casting

Fig. 23 Weibull distribution of tensile test results: (a) Elongation at fracture, (b) ultimate tensile strength for 0.2 cm³/100g Al hydrogen content

Fig. 24 Weibull distribution of tensile test results: (a) Elongation at fracture, (b) ultimate tensile strength for $0.4 \text{ cm}^3/100\text{g}$ Al hydrogen content

Fig. 25 Step mold that can be used both for gravity and low-pressure die casting: (a) Used as feeder for gravity castings and (b) closed. For LPDC: (a) Closed and (b) aligned with the riser tube to fill the cavity with counter gravity

samples had higher quality (i.e., lower bifilm content). Samples were collected from each step and subjected to density measurements for volumetric pore content and tensile tests for mechanical properties. The porosity distribution is given in Fig. 26.

As can be seen from Fig. 26, gravity die casted parts revealed higher volumetric porosity. At first, this situation

might be contradicting to the fact that lower the bifilm index lower porosity should be obtained. However, the pressure gradient generated during gravity casting depends upon the height of the feeder, and it decreases as the solidification is continued. On the other hand, for the LPDC, a pressure is applied that is left constant and continuous until the part is solidified. Therefore, even if there were a higher number of bifilms in the

Fig. 26 Volumetric porosity of cast parts with hydrogen content for the two melts cast as gravity and LPDC

Fig. 27 Tensile test results obtained from each step of the cast part: (a) Ultimate tensile test, (b) elongation at fracture for gravity die casting and LPDC

LPDC casting, the bifilms were not able to open up (unravel) to form the porosity. Thus, the porosity level was quite low. The most significant effect of bifilms was actually observed in the tensile test results. The casting with the higher bifilm index

(LPDC) revealed lower UTS and elongation at fracture with higher scatter as seen in Fig. 27.

From the tensile test results and bifilm index measurements of the experiments that have been carried out,

Fig. 28 Toughness, hydrogen content, and bifilm index correlation

toughness values for A356 alloy were also investigated.^[85] A contour plot was drawn from the hydrogen content, bifilm index, and toughness values. As seen in Fig. 28, the highest toughness was obtained with the lowest bifilm index regardless of the hydrogen content. As can be seen, even at the lowest hydrogen level, very low toughness values were measured when the bifilm index was high (bottom right corner of the plot).

CONCLUSION

Aluminum melt quality can be quantified by bifilm index using Reduced Pressure Test.

The RPT assessed by Bifilm length, possibly together with Bifilm number, probably remains the best quantification of metal quality. It has the additional benefits of simplicity and low cost.

Porosity phenomenon in aluminum castings is defined by the unravelling of the bifilms (growth stage), but not by the nucleation of hydrogen.

As bifilm index is increased, mechanical properties decrease.

It is estimated that high ductility can be obtained in the absence of bifilms.

ACKNOWLEDGMENTS

I would like to thank Prof. John Campbell for supervising my PhD thesis. I am thankful and gratified for all his help, assistance, guidance, and inspiration on all aspects.

Abstract

This article outlines the findings in the comparison of the influence of mechanical and electromagnetic stirring (EMS) on ingot long-term purity and uniformity during Ohno continuous casting (OCC). The magnitude of the average optimum velocity flow field and stirring parameters required to effectively purify aluminum ingots using mechanical stirring of the melt was determined and analyzed. Basing on the determined optimum mechanical flow field, electromagnetic parameters producing almost the same flow field near the interface were obtained through careful adjustments of parameters. Optimum parameters of the mechanical and EMS were obtained by numerically solving the solidification model coupled with either the multi-reference frame model (for mechanical stirring) or the magnetohydrodynamic model (for EMS) in CFD Fluent 6.3.26 software. For mechanical stirring, an optimum stirring intensity of 2 mm/min was determined whilst for EMS, the optimum magnetic field with an amplitude of 20 mT and a frequency of 2.7 Hz was determined, and these produced same magnitude optimum flow fields resulting in high-purity aluminum ingots. Comparison of the two methods showed that EMS is good in covering all the regions near the solid-liquid interface and is more effective in bulk melt mixing; thus it produces more uniform and purer ingots for longer casting times.

Keywords: Electromagnetic field; Interface; Computer simulation; Convection; Stirring.

INTRODUCTION

For the past three decades, high purity aluminum rods of superior quality have been produced by the Ohno continuous casting (OCC) process,^[1-3] and they are in high demand in the optoelectronics industry^[4,5] for audio and video cables applications. OCC process is a heated mold system that permits the production of net-shape or near-net-shape products with a high-quality surface, controlled solidification structure, and significantly enhanced properties. The detailed description of the OCC technology is found elsewhere.^[1,3] A solute boundary layer is accumulated at the solidification front during OCC casting because of segregation of different elements in the liquid or solid phase, and this solute-rich interface reduces the purity of the alloy ingot.^[6] A sufficiently strong convection in the melt toward the solidification front reduces the thickness of the boundary layer and purifies the ingot.^[6,7] The mechanism of purification involves breaking down dendrites extending from the liquid-solid interface into the liquid phase to release impurities between the dendrites or between the branches of the dendrites, and dispersing the

released impurities in the entire body of the liquid phase. This technique purifies ingots since the solute impurities will be continuously ejected from a solidifying ingot and transported into the bulk melt preventing back diffusion into the solid.^[7]

Several methods are known for inducing forced convection in the melt during solidification and mainly include ultrasonic, mechanical and electromagnetic stirring (EMS). Among the known melt forced stirring techniques, EMS is, perhaps, the most popular one as it is nonintrusive/contactless and offers direct and simple control of flow intensity through adjusting magnetic field parameters, thus producing efficient uniform stirring and desired heat and mass transport.^[8,9] This purifying technique of using EMS is now well established in purification of silicon containing trace impurities.^[10-14] Thus, control of solute transport and ingot properties with EMS is widely adopted in the field of solidification processing using various magnetic fields such as the fixed alternating magnetic field at induction heating, the high-gradient magnetic field and the rotating magnetic field. Mullin and Hulme^[15] observed that by applying rotating magnetic fields during zone refining, the diffusive boundary layer at the solidification

interface can be reduced. Many researchers, including,^[16–18] investigated the effect of electromagnetic parameters and stirrer design, intensity, frequency, location, length and orientation on various properties of produced ingots including purity and homogeneity. Using the numerical solution of magnetohydrodynamic (MHD) model, Marcelo et al.^[19,20] devised a constrained optimization algorithm that is capable of automatically determining the correct strengths, locations, and orientations of a finite number of magnets to produce the magnetic field force pattern that will create the specified concentration pattern in the fluid. Besides EMS, mechanical melt stirring using specially designed stirrers is a promising and competing technique since it is a simple, cheap and easy-to-use process.^[7,21,22] Thus, it is interesting to compare and contrast the influence of electromagnetic and mechanical stirring on ingot purity and evaluate the differences as a guide to operators. The influence of melt stirring on alloys grain refinement received a considerable attention^[23–25] but research of purification using stirring is still scarce except for silicon refinement. A number of studies have already been reported concerning grain refinement using forced melt convection,^[23–25] and only a few studies have been reported until now with respect to the interplay between alloy purification and EMS of the melt. Most of the researches on purification of alloys during solidification are on silicon purification for solar photovoltaic applications.

In this work, first, the optimum mechanical stirring velocity and resulting solute and flow fields required to eliminate the solute boundary layer are determined. Then, basing on the obtained velocity flow fields, the optimum magnetic field parameters (strength and frequency) required to produce the same magnitude velocity flow fields were computed. The numerical optimization of the mechanical stirrer rotation speed and magnetic field parameters was performed using the CFD Fluent 6.3.26 software. Subsequently, a comparison of the influence of mechanical and EMS on ingot long-term purity and uniformity was done.

SOLIDIFICATION MODEL

The governing equations based on the 1987 continuum formulation of Benon and Incropera^[26] were solved with the aid of user-defined subroutines in CFD Fluent 6.3.26 software.

Assumptions

1. All the properties of the mixture can be obtained from the properties of its individual components in each phase.
2. All transport properties of each phase, such as thermal and electrical conductivities or viscosity, are constants.
3. The densities are constant in each phase.
4. The mushy region is modeled by means of using the mixture viscosity.

5. Local equilibrium is assumed to exist at the solid–liquid interface i.e., the phase diagram applies.
6. The flow of the liquid phase is assumed incompressible, laminar, and Newtonian.
7. Solutes diffusion coefficients are isotropic and constant in each phase.
8. The electromagnetic characteristics of the melt are isotropic and uniform.

Based on the assumptions made above, the set of governing equations of mass, momentum, energy, and solute are formulated as shown in “Mass Conservation Equation” section below.

Mass Conservation Equation

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \vec{u}) = 0, \quad (1)$$

where ρ is the density, and $\vec{u}$ is the velocity vector.

Momentum Conservation Equation

$$\frac{\partial (\rho \vec{u})}{\partial t} + \nabla \cdot (\rho \vec{u} \vec{u}) = -\nabla p + \nabla \cdot (\mu_l \nabla \vec{u}) - \frac{\mu_l}{K} \vec{u} + S_m, \quad (2)$$

where p is the pressure, μ_l is the dynamic viscosity of the melt, K is the permeability constant of the mushy zone, and S_m is the momentum source that can be either due to mechanical or magnetic stirring.

Energy Conservation Equation

$$\frac{\partial (\rho H)}{\partial t} + \nabla \cdot (\rho H \vec{u}) = \nabla \cdot (k \nabla T) + S_h, \quad (3)$$

where H is the enthalpy, k is the thermal conductivity, T is the temperature, and S_h is the source term due to heat released in the solid–liquid interface during solidification.

The liquid fraction is assumed to be linearly proportional to temperature as follows:

$$f_l = \begin{cases} 1 & \text{when } T \geq T_l \\ \frac{T - T_s}{T_l - T_s} & \text{when } T_l \geq T \geq T_s \\ 0 & \text{when } T \leq T_s \end{cases} \quad (4)$$

Where, f_l is the liquid fraction, T_s is the temperature of solid, and T_l is the temperature of liquid.

Species Mass Conservation Equation

$$\begin{aligned} \frac{\partial (\rho C_i)}{\partial t} + \nabla \cdot (\rho [f_l \vec{u}_l C_{i,l} + (1 - f_l) \vec{u}_s C_{i,s}]) \\ = \nabla \cdot [\rho f_l D_{i,m,l} \nabla C_{i,l} + (1 - f_l) \rho D_{i,m,s} \nabla C_{i,s}] - S_c, \end{aligned} \quad (5)$$

where C_i is the total mass fraction of species i , $C_i = f_s C_s + f_l C_l$, D is the diffusion coefficient, and S_c is the source term governing the convective transport of solute rejected from the mushy zone. The subscripts i , l , c , m , and s represent the species number, liquid, convection, mixture, and solid, respectively.

The mixture quantities are defined by the following auxiliary relationships:

$$f_l + f_s = 1, H = H_L f_l + H_s f_s, D = D_L f_l + D_s f_s, k = k_l f_l + k_s f_s.$$

With the assumption of local equilibrium, the energy and species conservation equations are closed using the equilibrium phase diagram.

MECHANICAL STIRRING MODELING

Model and Implementation

The OCC process is represented in Fig. 1 and was simulated using the control volume-based commercial CFD Fluent 6.3.26 software, both in the presence and absence of mechanical stirring. Pressure-velocity coupling was

done with SIMPLE algorithm, and pressure was discretized by the PRESTO method. The ingot size used is of 58 mm diameter, and stirring was achieved through mechanical rotation of a stirrer propeller (43 mm × 4 mm) positioned at approximately 30 mm from the mold exit with the two-dimensional domain of interest as shown in Fig. 2. Momentum source terms due to mechanical stirring were introduced into the melt through Multiple Reference Frame model and source terms of governing equations (energy and solute) were introduced through User Defined Functions. Thermophysical properties of the dilute, industrial aluminum alloy together with the initial and boundary conditions used in the simulations are shown in Tables 1 and 2, respectively. The typical dilute industrial aluminum alloy is composed of copper and silicon as major impurities which are in small concentrations. The solid-liquid interface position was controlled to be near the stirring blades through adjustment of heat transfer coefficient of the water flux in the water spray region. Mechanical stirring was started after the process had reached steady state in order to allow the OCC process to quickly reach steady state. The optimum mechanical stirring rate was determined by increasing the stirring rate stepwise from zero and monitoring the ingot purity.

EMS MODELING

Configuration of the Physical Model

The arrangement of the electromagnetic stirrer position and orientation in the OCC mold is shown in Fig. 3. A given number of conducting coils with a given number of turns are stacked around the mold and near the solid-liquid interface in the electromagnetic stirrer. An alternating current with a given peak value of excitation current and frequency is passed through the solenoid coils that surround the heated mold to generate time varying magnetic field. The magnitude of the magnetic field depends upon the strength of the current and the number of turns in the coil.

The stirring is driven by the time dependent electro-magnetic field that interacts with the induced current in the aluminum melt to generate the steady-state Lorentz force field thereby inducing flow into the melt. The aim was to

determine the magnetic field parameters required to produce the same velocity magnitudes in the melt as those produced by mechanical stirring, illustrated in “Mechanical Stirring Modeling” section, through proper parameters adjustments.

Numerical Model

The solidification problem with EMS was solved in CFD Fluent 6.3.26 finite volume code. The Lorentz forces and distribution of magnetic field in the aluminum melt were calculated by solving the magnetic induction equation derived from Ohm's Law and Maxwell's equations,^[27] which is as follows:

$$\frac{\partial \vec{B}}{\partial t} + (\vec{u} \cdot \nabla) \vec{B} = \frac{1}{\mu \sigma} \Delta \vec{B} + (\vec{B} \cdot \nabla) \vec{u}, \quad (6)$$

where B denotes the flux density and u is the velocity of the melt fluid. The variables μ and σ describe the magnetic permeability and electrical conductivity of the melt ($\mu = 1.25\text{e-}6\text{H/m}$, $\sigma = 1.05\text{e}+7 \text{ } \Omega^{-1}\text{m}^{-1}$ for liquid Al), respectively. It is assumed that the alloy is above the Curie's temperature, so that its magnetic permeability is equal to magnetic permeability of the vacuum. The magnetic field is separated into an exterior, known field B_0 and a secondary induced field b , arising from the eddy currents induced in the liquid domain such that $B = B_0 + b$. The exterior field B_0 is the field arising from the stirring EMS coils, and it can be known from calculations using the coil dimensions and alternating current properties. The Lorentz forces are calculated from the superposition of magnetic fields $B_0 + b$ and the induced current density j by using the following relationship:

$$\vec{F} = \vec{j} \times \vec{B} = \vec{j} \times (\vec{B}_0 + \vec{b}). \quad (7)$$

Current density is then obtained using the following relationship:

$$\vec{j} = \frac{1}{\mu} \nabla \times \vec{B}. \quad (8)$$

This force term in Eq. 8 is subsequently added into the momentum equations as a source/sink term. The electromagnetic heat released into the melt is given by:

$$Q_{em} = \frac{j^2}{\sigma}. \quad (9)$$

This heat released is introduced as a thermal source term in the energy equation. For the present problem, the magnetic Reynolds number $Re_m = uU\mu\sigma$ is low so the induced current caused by the fluid flow was neglected. The magnetic field is calculated together with the flow field using a finite volume CFD-solver (computational fluid dynamics, CFD Fluent with MHD add-on). The simulation method uses the Fluent-specific user-defined scalar equations.

Fig. 3 Schematic illustration of OCC process with electromagnetic stirrer

Fig. 4 Solute redistribution obtained for (a) practical solidification according to literature^[29] and (b) using the numerical simulation with same experimental conditions in (a)^[22,28]

Here, the full coupling between the magnetic field and the fluid is considered. Boundary conditions for the Maxwell's equations used in the calculation of Lorentz force field are as follows: $\mathbf{J} \cdot \mathbf{n} = 0$ at the walls and the magnetic flux density B is continuous across the walls. The external magnetic field amplitude was adjusted to obtain the melt flow velocity strength near the interface same as that obtained using mechanical stirring. The magnetic field frequency was adjusted to get good melt penetration with flow cells close and separate to each other.

RESULTS AND DISCUSSIONS

Mechanical Stirring Results

The solidification model used in this work was validated elsewhere,^[22,28] where the model was tested and compared against experimental results from the literature.^[29] There was good agreement between practical compositional

results obtained (Fig. 4a) and simulation results (Fig. 4b) showing that the model is capable of computing the solidification process under consideration.

In mechanical stirring, a stirrer with its propeller blades is positioned in contact with the liquid–solid interface and the liquid phase can be stirred at the same time by the rotation of the blades as shown in Fig. 2. The cooling rate of the water spray is carefully adjusted such that the solid–liquid interface will be positioned just at the mold exit. Simulation results in Fig. 5 shows the aluminum metal redistribution in the melt, solid–liquid interface, and ingot after the OCC process has reached steady state in the absence of melt stirring. In accordance with Tiller,^[6] the solute redistribution is constant once steady-state condition is attained showing that equilibrium between solute rejection and transport into the melt is existing. Figure 6 shows the corresponding axial aluminum redistribution in the melt, solid–liquid interface, and ingot. Purification of the ingot occurs during the unsteady transient process before the solute boundary layer is established, and once

Fig. 5 Aluminum redistribution at steady state in absence of melt stirring

Fig. 6 Axial distribution of aluminum in absence of melt stirring

steady state is established, the aluminum ingot purity would be constant and slightly impure compared with the melt. Reduced ingot purity is due to continuous ejection of the solutes into the melt, thereby changing its composition with time and reducing ingot purity but this will occur after casting substantially long ingots.

The approximate critical stirring intensity required to produce ingots of highest purity during OCC process was obtained through rigorous trial and error simulations using different stirring rates (increasing from zero upward). Figures 7 and 8 shows the solute redistribution in ingot and its corresponding redistribution (near the center) in presence of the optimum melt stirring intensity of 2 mm/min for the casting of a 2 m long ingot. It is observed that stirring significantly increased the purity of the ingot to above 99.98% Al (Fig. 8) from about 99.70% Al (Fig. 6). Here aluminum purification mechanism is through breaking down solid extending from the liquid–solid interface (mushy zone) into the liquid phase to release impurities from between the dendrites or between the branches of the dendrites, and dispersing the released impurities in the entire body of the liquid phase as depicted in Fig. 9. Here solute rich fragments are removed from the dendrites

Fig. 7 Aluminum redistribution in presence of optimum melt stirring intensity of 2 mm/min, after casting 2 m ingot

Fig. 8 Axial aluminum redistribution in melt and ingot in presence of optimum mechanical melt stirring intensity of 2 mm/min, after casting 2 m ingot

and will dissolve into the bulk melt which is maintained at higher temperature. It should also be noted that in addition to transportation of solute rich solids into the bulk melt, solute rich melt in the mushy zone is also transported into the bulk melt and replaced by fresh melt which is not rich in solutes. When aluminum is solidified while dispersing the impurities in the entire body of liquid phase through forced convection, the formation of dendrites at the interface can be inhibited, permitting the melt to solidify while maintaining a smooth interface,^[7] and in this way convection will not disturb the flat interface.

The velocity profiles obtained using the optimum mechanical stirring intensity of 2 mm/min are shown in Fig. 10. The average velocity field distribution near the interface center was approximately 0.015 m/s. It is observed that the flow field is a one circular loop following the geometry of the stirrer and the solid–liquid interface at the peripherals is not effectively stirred. In order to improve the velocity flow fields during mechanical stirring, there may be a need of

Fig. 9 Aluminum enrichment mechanism from an interface

using many stirrers at different positions near the interface to effectively stir all the regions near the solid–liquid interface, and this is complicated and expensive in designing. It is also worth noting that the velocity flow fields are not very strong in the bulk melt away from the stirrer locus and such weak mixing is disadvantageous for solute transport.

EMS Results

Numerical simulation to study the influence of frequency and magnetic induction on flow field was performed, and after a rigorous systematic changing of parameters, it was found that at a frequency of $f=2.7\text{ Hz}$ and a magnetic induction of $B_0=20\text{ mT}$, an average velocity field of 0.0154 m/s was produced near the solid–liquid interface as shown in Fig. 11. This magnitude of the average velocity flow field is close to that for the optimum mechanical stirring determined in “Mechanical Stirring Results” section which was approximately 0.015 m/s on average. Here, it is observed that the EMS produced two axial convective loops perpendicular to the solid–liquid interface while stirring the melt, and it effectively stirred all the regions near the solid–liquid interface. A previous research has shown that axial stirring of the melt is stronger than tangential stirring and more effective in thinning the solute boundary layer.^[28,30–32] Moreover, the results in Fig. 11 also show that the frequencies required to produce optimum velocity flow fields are very small, yet they produce good penetration of the melt and a small body force that is just enough to eliminate the solute boundary layer as required. Although the velocity profiles near the solid–liquid interface are the same as those produced by mechanical stirring (Fig. 10), the velocity magnitudes produced by EMS in the bulk melt are larger than those produced by mechanical stirring. This likely produces better mixing

Fig. 10 Velocity profile in m/s for optimum mechanical melt stirring of 2 mm/min

for efficient transport of solutes thereby producing substantially longer, uniform, and higher purity ingots than those produced from mechanical stirring for a long time.

Analysis of the segregation in the aluminum ingot produced by EMS is shown in Fig. 12, which shows that axial (central) solutes fields in the ingot obtained are almost the same as those obtained from mechanical stirring (Fig. 7), except for a slight increase in ingot purity and slight decrease in melt aluminum content. This is likely to be due to uniform and consistent solute transport in EMS compared to mechanical stirring as explained before in the analysis of Fig. 11. It should be noted here that although the analysis of the solute fields was only done on the central part of the ingot, the purity of the ingots on the periphery during EMS is expected to be higher than that for mechanical stirring due to effective stirring in magnetic stirring as shown in velocity profiles in Figs. 10 and 11.

Using the computed magnetic field parameters (frequency and strength), the current and frequency of a specific stirrer can be determined and the magnetic stirrer can be designed analytically. The current intensity I required can be calculated using the following relationship:

$$B = \frac{1}{2} \mu N I \left(\frac{1}{\sqrt{L^2 + R^2}} \right), \quad (10)$$

where B is the induced magnetic flux density, μ is the magnetic permeability, N is the number of the coil windings, I is the current, L is the length of the coil, and R is the radius of the solenoid. The frequency of the alternating current induced in the coil can be known from the relation: $\omega = 2\pi f$, where f is the frequency of the alternating current.

Validation of the Magnetic Stirring Model

The capability of the CFD Fluent 6.3.26 magnetic induction method used to predict EMS during OCC process can be validated by comparing against the results obtained by Armour et al.,^[33] where electromagnetic melt stirring was

Fig. 11 Computed velocity field for $B_0=20$ mT and $f=2.7$ Hz. (a) Magnitude of the azimuthal velocity in m/s. (b) Streamlines of the meridian recirculation for optimum EMS

Fig. 12 Axial aluminum redistribution in melt and ingot in presence of optimum electromagnetic melt stirring intensity of $B_0=20$ mT and $f=2.7$ Hz

Fig. 13 CFX flow field for $f=10$ Hz and $B=2.0$ mT^[33]

used. The results obtained by Armour et al.^[33] are shown in Fig. 13. Comparing the result of flow fields in Fig. 13 with our results in Fig. 11 shows that the velocity profiles (in terms of orientation) obtained are in good agreement (as is expected of streamlines during EMS), demonstrating that the Fluent code used here is capable and valid in predicting EMS of the designed stirrer. In addition to this comparison, Noepfel et al. also obtained similar velocity flow fields during casting of binary Al-alloys in presence of EMS.^[30]

CONCLUSIONS

With the purpose of purifying an industrial aluminum alloy during OCC, the use of mechanical and electromagnetic melt stirring techniques was compared. The optimum stirring parameters (mechanical and electromagnetic)

for effectively stirring were determined. The following conclusions can be drawn:

1. To produce an almost similar optimum velocity flow field required for high purity ingots, an optimum stirring rate of 2 mm/min was determined for mechanical stirring and the optimum magnetic field with an amplitude of 20 mT and a frequency of 2.7 Hz was predicted for EMS.
2. The distribution of the velocity pattern near the solid-liquid interface was more uniform and covered the entire region in EMS when compared to mechanical stirring showing that magnetic stirring was effective in producing homogeneous ingots of higher purity.
3. EMS can produce substantially longer ingots of higher purity than mechanical stirring since it was more efficient in bulk melt mixing for solute transport compared to mechanical stirring.

Department of Metallurgy and Materials, University of Birmingham, Edgbaston, United Kingdom

Abstract

Guidelines for designing research on cast aluminium alloys have been developed to increase the reproducibility of results and make their interpretation more objective. These guidelines, based on the scientific method and recent research findings, are proposed for research on aluminium castings, but they can be easily adapted for other casting alloys.

Keywords: Aluminium; Scientific method; Reliability; Research design.

INTRODUCTION

Much has been accomplished in the last 20 years towards the understanding how cast metals perform under service conditions and how process variables affect their performance. When revisiting research on the performance of castings conducted in the past, it is natural to review the past records from the new perspective provided by new understanding. For such studies to be successful, drawing meaningful conclusions from such previous work, the details of the initial research have to be fully disclosed. However, it is a common experience to discover that many details in these past studies have been omitted. More seriously, however, these omissions continue to be made even up to the present time.

This paper is motivated by a strong need felt by the authors (which the authors believe will be shared by the entire casting research community) to assist, so far as possible, with the correction of this problem for the future. Critical details on precisely how past experiments were conducted are needed to allow the accurate interpretation or reinterpretation of results in the light of new data or new concepts. This desire is in keeping with the spirit and requirements of the scientific method, in which experiments should be reported in the detail that will allow the results to be confirmed by others.

In this paper, guidelines for research on aluminium alloy castings are provided. Similar guidelines should be developed for other alloy systems.

CASTING DEFECTS AND SCIENTIFIC METHOD

Structure, properties and performance of aluminium castings are influenced significantly by entrained bifilms, which, often

unknown to the researcher, preexist in suspension in the melt and/or are introduced during mould filling.^[1] Recent research has shown that entrainment defects affect structure by

- i. initiating gas and shrinkage porosity^[2]
- ii. nucleating second phase particles^[3,4]
- iii. interfering with the flow of liquid metal during solidification to influence secondary dendrite arm spacing (DAS) and grain size^[5]

They also have a strong effect on mechanical properties: their crack-like structure promoting premature fracture in tension^[6] and fatigue (essentially eliminating the crack initiation stage),^[7] and reducing ductility and tensile strength. Also influenced is the variability of properties, as evidenced by lower Weibull moduli.^[8,9] There is strong evidence therefore that both microstructural and mechanical property results reported for cast metals are directly related to the entrainment defect content of the metal. It is now understood that the defect content is determined by the molten metal quality and the filling system design.

Turning now to the authors' current concerns: in the scientific method, there are three strict criteria that must be fulfilled for research findings to be accepted provisionally as valid.^[10] These are reproducibility, completeness and objectivity. Bock^[10] states that 'acceptance of knowledge is always provisional, because scientists must always be ready to change their minds, or at least, reserve judgment, in the face of new contradictory evidence'. In fact, it seems perfectly justifiable to assert that if the three requirements of the scientific method are not met, the results and any model based on the results should be doubted.

It is well known that science relies heavily on the reproducibility of experiments and on receiving consistent, if not identical, results from them. This reproducibility depends on objective comparison of observations of different researchers studying the same phenomenon. It is the authors' opinion that such reproducibility is, with regret, more the exception than the rule in the metal casting literature. In fact, the casting literature is unfortunately characterised by an abundance of conflicting results, leading to major problems in the development of a logical framework for the discipline of casting science. As examples of conflicting results, two cases are presented below: the effect of Sr additions on β -plate length distribution in 319 and fluidity of A356.

Sr is a modifier known to be effective in assisting to control the deleterious β -phase in 319. Samuel et al.^[11–13] found that 250–350 ppm Sr was sufficient to neutralise the detrimental effects of the Fe rich intermetallics in 319, appearing to lead to the fragmentation of β -Al₅FeSi plates, but no α phase particles were observed. Samuel and Samuel^[13] stated that Sr dissolved the β -phase in the aluminium matrix without transformation into any other intermetallic phase. Samuel et al.^[11,14] reported that a Sr addition of ~300 ppm to a 319 alloy increased the average β -plate length slightly but decreased the number of particles per unit area (number density) and volume fraction by almost 66 and 61% respectively. Ashtari et al.,^[15] however, observed in their experiments with 319 that the length and volume fraction of β -phase decreased but the number density increased when 0.015% Sr was added to the alloy. The decrease in number density of β -phase with Sr addition led Samuel et al.^[11] to suggest that Sr poisons the nucleation sites for β -plates, in agreement with the bifilm model proposed above. However, in addition, Sr is known to form a compound with Al and Si with the formula Al₂Si₂Sr^[12,16]. Oxide bifilms were found to be favoured heterogeneous nucleation sites for the Sr rich intermetallics in A356 alloy^[17] as well as for the β -phase.^[18–21] Hence it can be speculated that Sr and Fe rich intermetallics compete for the same nucleation sites. Adsorbed Sr atoms, or a Sr rich phase may deactivate (or 'poison') some nucleation sites on areas of some oxide bifilms, interfering with the growth and coarsening of β -plates, increasing the number density and giving the impression that the β -plates are fragmented.^[22]

Many researchers investigated the effect of Sr additions on the fluidity of A356. Sr was found to slightly decrease,^[23] have no effect on,^[24] slightly increase^[25] or significantly increase^[26–28] fluidity. Sr addition was found^[29] to increase the oxide film content and average oxide film size in A356 alloy using both the liquid metal cleanliness analyser (LiMCA) and porous disc filtration apparatus (PoDFA) techniques. Since oxide content of the melt affects fluidity significantly,^[30,31] the variations in results can be interpreted to be due to different oxide inclusion content in the melts.

For good reproducibility of results between different researchers, it is clearly necessary, so far as possible, to have the same melt quality and the same design of filling system. However, there are practically no papers (with perhaps the exception of Ref. [31]) in which the melt quality was measured quantitatively and reported together with structure and properties. In addition, filling systems are very rarely described in papers even in the most respected journals. Hence almost all papers in the metal casting literature seem to fail the 'completeness' criterion, without which it is impossible to reproduce the experimental results. At the same time, a limited number of experimental results can be and are reproduced despite such opportunities for variability. For instance, the Weibull modulus, which has been used as a measure of reliability,^[32] has been found^[8,32–35] to be ~10 for the tensile strength of turbulently cast A356 alloys, but rising to 50 or more for material cast with good filling system designs.

A new set of guidelines is recommended for consideration during the design of the research, and which should subsequently be described in any publication made from the study. For simplicity and brevity, these guidelines are limited in this note to aluminium alloy castings. However, of course, these principles can be adopted and easily adapted for other nonferrous and ferrous alloys with minimal modification. The authors recognised that these proposals in themselves are not likely to be complete, but the authors believe them to be a useful start to which others will add from time to time.

NEW GUIDELINES

The details of the alloy composition and melt treatment should be disclosed:

- i. bifilm content: there is not a robust measure of the bifilm content at this time. However, the use of the reduced pressure test (RPT) to give the bifilm index (the total length of bifilms measured on a sectioned sample) together with the total bifilm number.^[36] These are likely to be a reasonable measure of the bifilm content at this time.^[37] Bifilms unfurl and inflate under the reduced pressure which makes the RPT a good tool for revealing and quantifying bifilm content. Other methods, such as QUALIFLASH^[38] and Prefil Footprinter^[39] are promising, and may be employed at the discretion of the researcher. Techniques such as LiMCA^[40] probably cannot be recommended. However, the RPT is so economical and so informative that it is recommended to be carried out at all times, in addition to any other test for quality, until such time as it can be demonstrated to have been superseded. The measurement method of bifilm content is outlined in Ref. [36]

- ii. Fe content: Fe bearing intermetallics have been shown^[3] to nucleate on the wetted side of bifilms and appears to cause them to unfurl during solidification, effectively increasing the crack size in the final casting. This appears to be the mechanism whereby iron reduces the tensile strength and ductility of Al alloy castings. An analysis of the metal must therefore include an analysis of the iron content. Manganese also adds to the volume of iron intermetallics, and most probably should also be analysed and reported
- iii. hydrogen content: hydrogen, rejected ahead of the freezing front, inflates and unfurls the bifilms (which are also being pushed and concentrated ahead of the advancing solid) and therefore affects the maximum crack size in the solid metal.^[1] The RPT is not a good indicator of hydrogen content and is therefore not recommended as a hydrogen test.^[36,37] A fundamental technique for hydrogen in solution is recommended, such as those based on the determination of the pressure of hydrogen in equilibrium with the melt by direct contact measurement or remotely by circulation of a carrier gas through the metal
- iv. grain refinement: the addition of grain refining agents to the melt, such as those based on Ti and B, results in the precipitation of Ti bearing phases on bifilms in the liquid metal. If the melt is not agitated, those bifilms with Ti bearing phases on them sediment to the bottom of the ladle (or holding furnace).^[41–43] In this way far fewer bifilms are transferred to make the casting (unless, of course, a bottom pouring ladle is used) with a consequential benefit to the properties of the casting that may exceed the effects of the finer grain size. Hence it is necessary that the amount of Ti and B addition and the details of the technique used for the addition process have to be disclosed
- v. dwell time after the addition of grain refiner: If the melt is stirred immediately before pouring, the benefits of the cleaning of the melt from suspended bifilms as a result of sedimentation may be lost. Therefore the dwell time between the addition (usually dispersed and homogenised by stirring) and the pouring of the melt should be disclosed
- vi. the holding temperature should also be specified as Samuel and co-workers^[14] showed a composition related threshold temperature for this effect
- vii. transfer details: complete details about whether/how the liquid metal is transferred from the melting furnace to where it is poured into the moulds should be given. The importance of care in handling during the transfer of metal has been illustrated in measurements such as those carried out by Dispinar and Campbell.^[44] If a transfer ladle or crucible is used, its size, material and preheat temperature needs to

be specified, because the amount of convection is strongly affected by the ladle size per se, and the rate of loss of heat from the top, and through the bottom and sides. The resultant convective stirring of the melt will be expected to influence the effectiveness of any sedimentation effect, and thus the final cleanness of the melt before pouring (provided no stirring is attempted immediately before pouring). The length of time that the melt remains in the transfer ladle is also relevant of course, and should be noted

- viii. amount of modification: Sr or Na additions for modification deactivate the bifilms as favoured substrates and therefore limit their ability to serve as nucleation sites for Si eutectic particles,^[45] and Fe bearing b-plates. The quantity of additions as well as the duration between the time of addition and the time of pouring needs to be disclosed.

The following details about the mould and pouring should also be disclosed

- ix. the complete geometry of the filling system should be given: it has been established that the formation of entrainment defects is sensitive to even the small details of the filling system.^[46] It should be borne in mind that most current filling system designs introduce up to 50% air into the flow. To the authors' knowledge, this aspect of poor filling system design has not received the attention it deserves. The discharge coefficient (the ratio of the actual liquid metal discharged, compared to the theoretically expected amount of metal assuming frictionless flow) measured at the base of many sprues used in commercial filling systems is often found to be significantly less than 1.0, usually yielding values in the region of only 0.4 to 0.7. This ratio often indicates a significant content of air in the flow, but some of the reduced discharge effect is the result of friction against the walls of the sprue. However, for 'reverse tapered' sprues, commonly provided by many automatic moulding machines, the contribution of friction is practically zero. Thus the values of discharge coefficient typically in the region of 0.5 can now be interpreted unambiguously, corresponding closely to an air content of ~50%.

If the filling system is designed poorly, any attempt to explain the results or to reproduce the conditions will be difficult if not impossible. It is with regret that the authors note that most current casting research uses poor filling systems, but not even these are described in adequate detail. Furthermore, there is good reason to believe that those bifilms created by the filling system are the most important for the control of the structure and properties of the casting.^[1,2] For design of filling systems that will produce minimum or zero entrainment defects, the reader is advised to scrupulously follow

the latest developments in filling system design.^[45] The following details are a summary of the most important features that are required to be designed and made with care, and fully described in any ensuing publication of findings:

- a. pouring basin design: badly designed basins, particularly the common funnel shaped or conical basin, introduce harmful quantities of air and turbulence into the filling system. No research should be carried out with the poor entrance conditions provided by these types of basin. (A possible exception is the case where the sprue entrance is only a very few millimetres in diameter. In such cases surface tension assists to fill the entrance successfully, excluding the entrance of air.^[45] Other important exceptions will be evident to the discerning researcher, as in the case of tilt filling of moulds, and the prepriming of the sprue or other sections of the filling system)^[47]
- b. preferred use of a stopper in the sprue entrance to ensure pouring basin is filled to the correct depth before the removal of the stopper
- c. specification of the height between pouring ladle and pouring basin (this height provides additional acceleration to the liquid metal)
- d. specification of the pouring direction (it is useful to 'over-pour' the sprue entrance to avoid direct pouring into the sprue)
- e. specification of the down sprue design: whether the sprue was tapered hyperbolically, straight taper, zero taper, or reverse taper. Sprue shape and dimensions are critical
- f. specification of all radii for at least all the inside corners of all bends
- g. specification of any filter used in the filling system. Its dimensions, type (extruded, pressed, sintered, foam, glass cloth, steel mesh, steel wool, etc.), pore size, location, and print design preferably to reduce reoxidation of the melt on exit from the filter^[2]
- h. specification of design of runner (above or below gates, tapered)
- i. specification of any cross trap size and location (preferably above runner)
- j. specification of design and location of ingate(s).
- x. mould materials: permanent (metal) moulds and investment moulds are usually inert towards the casting. However, moulds made from bonded aggregates such as silica sand use a wide variety of binders. The binders (water, clay, resins or other chemicals) are usually chemically reactive with the

melt and the cooling casting, and thus are required to be specified in detail

- xi. core materials: gases may be produced by cores. The details of the aggregate require specification, including its mineral name such as silica, olivine, norite, etc., its average grain size and/or its grain size distribution, and the core binder. So far as possible, all cores should be adequately vented to avoid bubble damage by 'core blows'^[45]
- xii. chills and fins: chills and fins increase the cooling rate and limit the unfurling of bifilms (a time dependent process^[1]) thus raising the properties of cast metal. Inadvertent fins (including accidental flash because mould halves were not held together sufficiently tightly) should be recorded since this can significantly affect the rate of cooling of the casting, particularly in the locality of the flash.

DISCUSSION

It is the view of the authors that many publications in the casting literature have failed to follow the scientific method, and, unfortunately, are continuing to do so. Therefore, readers of the casting literature are advised to be critical about the experimental details of much of the incompletely reported work available at this time, as interpretations and models built on such past results may be misleading. As a result of the failure to deliver the complete information required for understanding, much subjectivity (as opposed to 'objectivity') and speculation have to be injected into the explanations.

The list presented above to promote the completeness of reporting may be daunting and unwelcome in view of its length to researchers in the field. However, of course, once written up in detail in an accessible journal, most of the details need only be referenced thereafter for economy of writing and presentation. Only changes to the technique need then be reported. The adoption and possibly further refinement of these guidelines is intended to benefit the science of casting, with a view to such improved understanding leading to enhanced benefits in casting technology.

CONCLUSIONS

A new set of guidelines for the design of research on metal castings, particularly aluminium alloy castings, has been proposed. They are intended to assist researchers to design experiments that will yield reproducible and understandable results.

The authors invite the scientific community to encourage the use of the guidelines, revising and updating them as necessary, and develop similar guidelines for other casting alloys.

ACKNOWLEDGEMENT

The authors thank Professor N. R. Green, The University of Birmingham, UK for useful comments.

Metallic Coatings for Brazing Aluminum Alloys

A. A. Suslov

Tekhnomash Scientific and Production Association, Russia

Abstract

Because of their high specific strength and satisfactory corrosion resistance, aluminum alloys belong to the group of fundamental structural materials in modern engineering. Their wide use has been made possible as a result of developing advanced methods of processing and producing permanent joints by welding or brazing. However, the application of brazing aluminum alloys is limited because of the problems in removing the strong and chemically resistant oxide film. These problems can be overcome by using metallic coatings which themselves do not oxidize during heating in vacuum and, when deposited, the oxide film is broken up and can be removed from the surface of the parent material. The most promising method is to use metallic coatings in the form of individual components of the brazing alloy which forms in contact melting of the deposited coatings with aluminum in heating for brazing. This brazing method is referred to as contact-reactive brazing and is used widely for brazing aluminum alloys. This article provides an overview of the contact-reactive brazing process.

Keywords: Contact-reactive brazing; Metallic coatings; Thermal vacuum spraying.

Because of their high specific strength and satisfactory corrosion resistance, aluminium alloys belong to the group of fundamental structural materials in modern engineering. Their wide use has been made possible as a result of developing advanced methods of processing and producing permanent joints by welding or brazing.

However, the application of brazing aluminium alloys is limited because of the problems in removing the strong and chemically resistant oxide film. This film does not dissociate in the vacuum which can be achieved in brazing, does not dissolve in the parent material and is not reduced by active gas media such as hydrogen or boron trifluoride used efficiently in brazing other metals and alloys.

These problems can be overcome by using metallic coatings which themselves do not oxidise during heating in vacuum and, when deposited, the oxide film is broken up and can be removed from the surface of the parent material.

Coatings are deposited by electroplating and thermal vacuum spraying. With the former, the removal of the oxide film from the surface takes place as a result of deposition of an intermediate layer (prior to electroplating) of a more electropositive metal than aluminium. With the latter method, direct contact of the metal of the coating with aluminium is ensured mainly by disrupting the oxide film by rapidly flying particles of the sprayed metal in glow discharge.

The most promising method is to use metallic coatings in the form of individual components of the brazing alloy which forms in contact melting of the deposited coatings

with aluminium in heating for brazing. This mechanism of formation of a liquid brazing alloy is possible when the area of contact of the metal of the coating with the parent material is characterised, as a result of solution and diffusion processes, by the formation of an eutectic alloy with a lower melting point than in the aluminium alloys being joined. This brazing method is referred to as contact-reactive brazing and is used widely for brazing steels, titanium and aluminium alloys.

With this method of brazing aluminium alloys, copper and silver are the most suitable as coating metals. They do not oxidise during heating in vacuum and form with aluminium relatively low-melting eutectic alloys at a temperature of 548 and 558°C.

The experimental results show that in contact-reactive brazing aluminium alloys, the quality of brazed joints depends strongly on the coating method. The best results as regards the strength of brazed joints, spreading of the resultant brazing alloys and formation of brazed joints are obtained when depositing coatings by thermal vacuum spraying. With brazing with a coating deposited by electroplating, the resultant brazing alloy spreads poorly over the surface of the parent material and, consequently, the fillets of brazed joints are non-uniform and intermittent.

Gas analysis results (Table 1) show that in contact melting of AD1 aluminium with a copper coating deposited by electroplating, the quality of the generated gases is considerably higher than in thermal vacuum spraying. Hydrogen generates in contact melting of aluminium with the coating metal.

Table 1

Coating method	Temperature °C	Amount of generated gases, 10 ⁻³ cm ⁻³ , per 1 cm ² of surface of the specimen					
		H ₂	CO	CO ₂	H ₂ O	Total gases	Total amount of gases
Electroplating	20–300	24.4	0.37	0.23	0.66	25.66	31.62
	300–600	4.15	0.09	0.18	0.94	5.96	31.62
Thermal vacuum spraying	20–300	0.15	0.37	0.07	0.01	0.22	2.19
	300–600	1.48	0.03	0.35	0.11	1.97	2.19
Without coating	20–300	0.53	0.53	0.21	0.12	1.39	5.38
	300–600	2.05	0.92	0.62	0.4	3.99	5.38

This takes place as a result of the fact that in electroplating, the surface layers of the parent material adsorb a large amount of moisture which forms hydroxide compounds with aluminium. In heating, hydroxide compounds dissociate in accordance with Taber's series:

The moisture released in dissociation of the hydroxide interacts with aluminium by the reaction

The oxide film, formed as a result of these reactions below the metal coating, rises during contact melting to the surface of the liquid phase of the brazing alloy and complicates its spreading and formation of brazed joints.

The metallic coating deposited by thermal vacuum spraying protects the aluminium surface against oxidation during heating for vacuum brazing up to the moment of formation of the brazing alloy. When the brazing alloy forms, the oxide film does not manage to form and even if it forms, it can easily be disrupted in spreading of the brazing alloy on the surface of the parent material as a result of its small thickness and density. This ensures direct contact of the brazed surfaces and formation of brazed joints.

The properties of the brazed joints were determined on lap specimens of 1911, AMts and AMtsPS aluminium alloys (AMts alloy clad with silumin with a silicon content of

8–9.5%). Copper and silver were deposited on the surface of the specimens by thermal vacuum spraying. Spraying experiments were carried out in UV-800M vacuum equipment with specially developed devices for securing and moving the specimens during spraying. These devices made it possible to produce silver and copper coatings with a uniformity of 2–3 *f*μm and a minimum consumption of metal.

As a result of developing the process, it was possible to determine the optimum physico-technological spraying parameters: substrate temperature 150–170°C; deposition rate 0.4–0.5 jan/min; residual gas pressure (1–2)10⁻⁴ torr. At the given substrate temperature, the distance between the substrate and the evaporator was 100–150 mm and the angle of orientation of the specimens in relation to the flow of evaporated metal was 100–120°. The thickness of the sprayed layer of copper coating and silver was 20–25 μm.

Lap specimens were brazed in a standard vacuum furnace with a residual pressure in heating of 133×10⁻⁴ – 665×10⁻⁵ Pa. The composition of brazing alloys formed in contact-reactive brazing, the brazing conditions and the properties of brazed joints are presented in Table 2. It can be seen that the highest strength is shown by the joints brazed with a silver coating. However, joints brazed using silver as the coating metal contain > 70% of this scarce metal, and joints brazed with the copper coating have high strength.

When using as the parent material AMtsPS alloy clad with silumin, contact-reactive brazing through copper and silver coatings resulted in the formation, in the composition of brazed joints, of eutectic alloys with a lower silver

Table 2

Parent material (alloy)	Metal of the coating	Composition of brazed joint, %				Brazing temperature, °C	Shear strength of brazed joints, MPa
		Al	Ag	Cu	Si		
1911	Silver	28	72	–	–	570–580	185
AMts clad with silumin	Silver + copper	45	27	24	4	530–540	107
As above	Silver	60	35	–	5	560–570	156
As above	Copper	66	–	28	6	550–560	77
AMts PS	as above	67	–	33	–	560–570	72

content and a higher strength of brazed joints in comparison with brazing with the copper coating. Contact-reactive brazing of aluminium alloys in vacuum greatly expands the technological possibilities of producing sections of aluminium alloys, and markedly increases the quality and reliability of brazed joints.

CONCLUSION

The process of contact-reactive brazing aluminium alloys in vacuum using a copper or silver coating deposited by thermal vacuum spraying gives brazed joints with sufficiently higher mechanical properties.

Metallography of Aluminum Alloys: Atlas of Microstructures

S.V.S. Narayana Murty, Sushant K. Manwatkar, and P. Ramesh Narayanan

Material Characterisation Division, Materials and Metallurgy Group, Vikram Sarabhai Space Centre, Thumba P.O., Trivandrum, Kerala, 695 022, India

Abstract

Microstructure plays an important role in obtaining the desired properties in metallic materials in general and aluminum alloys in particular. Mechanical properties of aluminum alloys can be significantly altered by changing the microstructure. No other alloy system can boast of as many temper conditions as aluminum alloys. With the progress in the understanding of microstructure–mechanical property relationships in these materials, “tailor made” alloys to meet specific demands are being industrially developed. The broad spectrum of aluminum alloys in wide range of temper conditions offer materials with widely varying mechanical properties for structural designers. In order to select aluminum alloys with the desired properties for the intended application, it is essential to understand the role of microstructure under actual service conditions. It is in this context “Metallography of aluminum alloys” becomes very important. This chapter provides an insight in to the microstructural evolution of aluminum alloys from the as-cast condition to the final product. Typical examples of microstructural evolution in different aluminum alloys under various thermomechanical conditions are presented here. An atlas of microstructures of commercial and experimental wrought and cast aluminum alloys is presented in an appendix to this book. This appendix includes optical photomicrographs of both cast and wrought alloys and scanning electron micrographs of polished surfaces as well as fracture surfaces of various aluminum alloys as well as transmission electron micrographs as separate annexure. Readers are encouraged to go through the optical microstructures and fractographs along with this chapter for better understanding of the evolution of microstructure as a function of alloying additions, thermomechanical processing conditions, and fracture behavior under tension.

Keywords: Metallography; Aluminium alloys; Optical microscopy; Scanning electron microscopy; Transmission electron microscopy; Failure analysis; Atlas of microstructures.

INTRODUCTION

Aluminum alloys, by virtue of their high-strength-to-density ratio, resistance to catastrophic failure, high degree of toughness, ease of fabricability, and availability in range of temper conditions are the most widely used materials in the aircraft and aerospace industries.^[1] High-strength aluminum alloys are used in different forms like plates, sheets, forgings, extrusions, and welded and machined components. These alloys are the choice of materials to work at cryogenic temperatures. They are also used in a number of architectural applications due to their amenability for anodisation to various hues.^[2,3] Further, the ever-increasing demand for more fuel-efficient vehicles to reduce energy consumption is a challenge for the automotive industry and characteristic properties of aluminum, viz., high specific strength/specific stiffness ratio, good formability coupled with excellent corrosion resistance, and recycling potential make it the ideal candidate in automobiles.^[4] Another important role of aluminum alloys is in the overhead power transmission electrical conductor wires.^[5]

Aluminum alloys can be heat treated to impart improved strength by precipitation hardening. Precipitation improves the yield strength of the alloys because the precipitates impede dislocation motion through the material. The magnitude of strengthening depends on the morphology of the precipitates, which in turn is governed by the interfacial and strain energies of the precipitate/matrix system. These interfacial and strain energies are sensitive to the nature of the crystal structure of the precipitate phase, the matrix phase, and the interface between the two. Colossal contributions have been made in understanding the relationship between composition, processing, microstructure, and properties leading to newer compositions of aluminum alloys with improved performance.^[6–8] Significant advancements in the melting and casting practices, tight compositional control, especially in terms of Fe and Si impurity levels, and an understanding of the homogenization and heat treatment cycles have led to the development of alloys with improved strength, fracture toughness, corrosion resistance, and fatigue crack growth resistance.

Table 1 Aluminum alloys with Principal alloying elements, possible strengthening precipitates, and their typical applications

Alloy designation	Principal alloying addition with possible strengthening precipitates	Typical commercial alloys	Typical applications
1XXX	99.0% minimum aluminum strain hardenable alloys	AA1100	Foil, electrical conductors
2XXX	~4%–5% Cu (with additions of Mn, Si, Mg, Li) precipitation hardenable alloys with plate shaped θ' (Al_2Cu), S' (Al_2CuMg), and needle-shaped T_1 (Al_2CuLi) precipitates	AA2014, AA2024, AA2219, AA2195, AA2618	Air frames, welded propellant tanks for cryogenic fluids, air frames, forgings, extrusions
3XXX	1% Mn (and Mg) strain hardenable alloys	AA3003	Beverage cans, food containers
4XXX	Al-Si alloys	AA4043	Filler wire
5XXX	~5% Mg (with Cr, Mn) strain hardenable alloys	AA5083, AA5454, AA5086, AA5456	Excellent formability and weldability, corrosion resistance, structural applications, forgings
6XXX	Up to 1% Mg and Si precipitation hardenable alloys with β'' (Mg_2Si)	AA6061, AA6083, AA6351	Extrusions, architectural applications
7XXX	Up to 8% Zn (with Mg, Cu) precipitation hardenable alloys with plate shaped η'	AA7010, AA7050, AA7055, AA7075, AA7085, AA7175	High-strength alloys, weldable alloys, air craft structures
Cast	13% Si (with Mg, Cu) with Na additions	A319, A356	Automobile applications

Aluminum alloys are classified into eight series depending on the major alloying elements used. The typical alloying elements, strengthening precipitates, and typical applications of various aluminum alloys are detailed in the Table 1. Depending on the processing route, alloys are broadly divided into two major categories, namely, (a) cast alloys and (b) wrought alloys. Wrought aluminum alloys could further be subdivided into two categories: heat-treatable and non-heat-treatable aluminum alloys, depending on the typical processing routes that are applicable to render them industrially usable.

METALLOGRAPHY OF ALUMINUM ALLOYS

Microstructure of materials is key to the understanding of their properties, and metallographic examination is an important tool in the design, development, qualification, and usage of materials. Simplicity coupled with cost makes optical metallographic examination the most popular method of observing macro- and microstructure of alloys. It will reveal the effects of thermomechanical processing, heat treatment, and service conditions to which the alloy has been exposed.

Aluminum alloys cover a wide range of chemical compositions and can be treated to different temper conditions resulting in a range of hardness values. Therefore, metallographic specimen preparation techniques also vary considerably for the observation of microstructure by optical microscopy. Softer alloys are difficult to prepare by conventional mechanical polishing techniques and are often

easily polished by electrolytic methods to circumvent the problems posed by the embedding of the abrasive particles used for mechanical polishing. On the other hand, harder alloys are easier to prepare and possess a wide variety of microstructures and phases depending on the type of alloy and thermomechanical processing history. Figure 1 shows the spectrum of wrought and cast aluminum alloys used in aerospace and other applications.

Most of the changes that become apparent during the microstructural evaluation of aluminum alloys occur during the processes starting from solidification of liquid metal, homogenization of the as-cast ingot, hot and cold working, solution treatment and precipitation hardening. A good interpretation of the microstructure depends on having the complete history of the material being analyzed. In cases where the complete history of the material under study is not available, comparative samples with known history will help in the interpretation of the microstructures. It is in this context that an atlas of aluminum alloy microstructures is useful and relevant and is presented in the appendix to this book. Table 2 presents some important temper designations of commercial aluminum alloys and product forms for ready reference.

In general, examination of the material starts with normal visual observation and proceeds to higher magnifications as per the need for detailed interpretation. This will facilitate examination of the bulk of the sample and selecting the area of interest for high magnification observation as the area of observation becomes small at higher magnification. Figure 2 shows the photograph of a failed aluminum alloy component along with the optical

Fig. 1 Spectrum of wrought and cast aluminum alloy materials and fabricated components

Table 2 Some important temper designations of commercial aluminum alloys and product forms

Temper	Description	Alloy designation	Product forms
F	As fabricated	All	All
O	Annealed	All	All
T3	Solution heat treated, cold worked, and naturally aged to a substantially stable condition	2011, 2014, Alclad 2014, Alclad 2024	Sheet; rolled or cold finished rod bar or wire; drawn tube and extruded tube, wire, rod, bar and profiles (2024 only)
T351	Solution heat treated stretched a controlled amount for stress relief and naturally aged (No further straightening after stretching)	2024, Alclad 2024, 2124, 2219	Plate; rolled or cold finished bar (2024 only)
T3511	Same as T3510 Minor straightening after stretching to comply with standard tolerances	2024, 2219	Extruded tube, wire, rod, bar and profiles
T4	Solution heat treated and naturally aged	All (with exceptions)	All (most with exceptions)
T5	Cooled from an elevated temperature shaping process and then artificially aged	6063, 6005, 6005A, 6105, 6162, 6351, 6463	extruded tube, wire, rod, bar and profiles
T6	Solution heat treated and then artificially aged	All (with exceptions)	All (with exceptions)
T651	Solution heat treated stretched a controlled amount (product dependent) for stress relief and artificially aged (No further straightening after stretching)	2014, 6061, 6262, 7075, 7178, 7475, Alclad 2014, Alclad 6061, Alclad 7075, Alclad 7175, Alclad 7475	Plate (most with exceptions) rolled or cold-finished rod and bar (most with exceptions)
T6511	Same as T6510 except minor straightening allowed after stretching to comply with standard tolerances	2014, 6061, 6066, 6162, 6262, 7075, 7178	extruded tube (except for 6162 and 7178), wire, rod, bar and profiles
T652	Solution heat treated compressed to a permanent set of 1%–5% for stress relief and artificially aged	2014, 6061, 6151, 7075	Forging and forging stock

(Continued)

Table 2 Some important temper designations of commercial aluminum alloys and product forms (*Continued*)

Temper	Designation	Temper alloy	Product forms
T7	Solution heat treated and artificially overaged/stabilized to control important properties (rarely used without second digit as below)	7050	Rivets
T72	Solution heat treated and artificially aged by user from O or F temper (not available from producer)	2024	Sheet
T73	Solution heat treated fully overaged artificially to achieve best corrosion resistance with a greater reduction in strength than T74	7049, 7075, Alclad 7075	Sheet (7075 and Alclad 7075): drawn and extruded tube (7075): extruded wire, rod, bar and profiles (7075): rolled or cold-finished rod, bar and wire (7075): rivets (7075): forgings and forging stock (7049 and 7075)
T7351	Solution heat treated stretched a controlled amount (product dependent) for stress relief, and artificially overaged to achieve best corrosion resistance with a greater reduction in strength than T74 ((No further straightening after stretching)	7075, Alclad 7075	Plate (7075 and Alclad 7075), rolled or cold-finished rod and bar (7075)
T74	Solution heat treated and then artificially overaged to achieve corrosion resistance and strength level between the T73 and T76 temper	7050	Forgings and forging stock
T7451	Solution heat treated stretched a controlled amount for stress relief (product dependent) and then artificially over aged to achieve corrosion resistance and strength level between the T73 and T76 temper (no further straightening after stretching)	7050	Plate
T7452	Solution heat treated compressed to a permanent set of 1%–5% for stress relief and artificially overaged to achieve corrosion resistance and strength level between the T73 and T76 tempers	7050	Forgings and forging stock
T7651	Solution heat treated stretched a controlled amount for stress relief (product dependent) and artificially overage to achieve moderate corrosion resistance with some reduction in strength relative to the T79 temper (no further straightening after stretching)	7050, 7075, Alclad 7075, 7178, Alclad 7178 7475, Alclad 7475	Plate
T8	Solution heat treated cold worked, and then artificially aged	2011	Drawn tube, rolled or cold-finished rod, bar, and wire
T81	Solution heat treated, cold worked ~1% and then artificially aged	2024, Alclad 2024, 2219, Alclad 2219	Sheet, Extruded tube, wire, rod, bar, and profiles
T851	Solution heat treated stretched a controlled amount for stress relief (product dependent) and then artificially aged (no further straightening after stretching)	2024, Alclad 2024, 2219, Alclad 2219	Plate rolled or cold-finished rod and bar (2024 and 2219)

microstructure and scanning electron micrograph. This example illustrates the need for careful visual observation of the failed component for the presence of defects followed by meticulous sectioning of the component for further optical and fractographic analysis for determining the reasons for failure. Wherever substructure

examination is required for the shape, size, and distribution of precipitates or for other finer details, transmission electron microscopy (TEM) is performed to view the microstructure at higher magnifications and resolutions. A TEM fitted with an energy dispersive spectroscopy (EDS) is useful to provide the chemical composition

Fig. 2 (a) Photograph of a cracked aluminum alloy AA7075 component; (b) low magnification fractograph of the cracked surface; (c) optical microstructure of the same; and (d) fractograph of the failed component

of the phases present in the microstructure and vital information about the material.

The examination of fracture surfaces is essential to determine the mode of failure and is performed initially using a stereo microscope and subsequently at higher magnifications and resolutions using a scanning electron microscope (SEM). Care must be exercised in handling the specimens such that the fracture surfaces are preserved without any contamination or loss of features by rubbing. This is particularly important in conducting the failure analysis of components, where the information obtained from the fracture surface is vital to understand the origin and cause of failure.^[9–12] Figure 3 shows the photograph of failed rivets and closer observations in SEM to reveal the mode of failure. It can be seen that the low magnification stereo microstructure observation of failed rivets reveals distinctly different regions (A and B). Region A shows more ductile features in the form of dimples compared to region B which has more of flat features. The 45° slanted fracture in visual observation coupled with flat features in fractography indicates that the rivets failed by shear loading. On the other hand, the same alloy when tested in tension reveals fine equiaxed dimples indicative of ductile fracture.

OPTICAL MICROSCOPY OF ALUMINUM ALLOYS

Optical microscopy is the most common and important tool for microstructural examination of aluminum alloys. It is useful up to magnification of about 2500× where features as small as 0.1 μm can be resolved. In the as-polished condition, optical microscopy provides information on size, shape, and distribution of second-phase particles; presence of casting/welding defects such as porosity and cracks; eutectic melting due to overheating and presence of extraneous inclusions. After etching with a suitable chemical, the microstructure reveals the shape and size of the grains, sub-grains, phases present, features resulting from thermomechanical processing such as grain orientation and slip lines within the grains. However, optical microscopy cannot reveal the precipitates that are responsible for the age hardening or other substructure information such as the presence of dislocations, for which electron microscopy is essential. Further, the identification of intermetallic phases present in the aluminum alloys is important because their shape, size, and distribution can affect the mechanical properties. These phases are the consequence of equilibrium or nonequilibrium reactions occurring in

Fig. 3 Photographs of aluminum alloy AA2014 rivets failed during assembly of a structure. A low magnification picture (bottom left) along with fractographic observations of the regions A and B marked (right) present two different features. Photomicrographs of rivets tested in tension are presented for comparison

the alloy due to solidification conditions and subsequent thermomechanical processing.^[13,14] Metallography of aluminum alloys is usually conducted on polished and etched specimens as a part of research and development on advanced materials, as a part of quality control measures for the presence of defects and for failure analysis investigations.^[15,16] Microstructural examination of aluminum alloys requires a well-executed series of steps meticulously developed based upon scientific understanding and practical experience. The steps required to prepare specimens suitable for metallography progressively consist of sectioning, mounting, grinding, polishing, and etching.

Sectioning is essential in most cases to obtain a small piece for metallographic examination. However, metallography on large components is still possible without the necessity of sectioning. While in the former case, the specimen is brought to metallography laboratory, metallographic tools are taken to the site to evaluate the microstructure on large-sized components in the latter case, and this is referred to as “nondestructive”, on-site, in-situ metallography. This is specially dealt with in a separate section at the end of the chapter. In the case of sectioning of a sample from bulk, care should be taken to ensure that the sample is a true representation of the bulk material. Mounting of

the sectioned specimen in a thermoplastic or thermosetting resin is usually carried out for small specimens which are difficult to handle or where microstructural features at the edge are required. However, mounting is not required in cases where the specimens are big enough to handle without any difficulty.

After the completion of polishing, it is a good practice to microscopically examine the surfaces before etching. Microscopic examination in as-polished condition provides important information about the presence of inclusions, porosities, eutectic melting, excessive heating of material during solution heat treatment and the presence weld defects such as chain porosities, aligned porosities, and cracks. Etching of the specimens with a suitable reagent is performed to reveal the grain and sub-grain structure, constituent phases, detect segregation, orientation of grains, effects of cold work, and to reveal grain size. The procedures followed for microstructural evaluation are presented briefly in the following sections.

Sectioning

Aluminum alloys are relatively soft and can be sectioned by any standard cutting technique. However, care should be taken to reduce the amount and depth of damage produced at the sectioned surface. An abrasive cutoff saw produces relatively smooth surfaces with little damage by properly choosing the wheel, suitable cooling, feed rate, and pressure. A precision diamond saw with small diameter thin blades produces little surface damage and excellent surface finish. Overall, cutting must not produce excessive temperatures that can alter the microstructure and hardness; hence, dry cutting should be avoided. A lubricant for cutting is used to avoid temperature increase and structural modification of the specimen.

The same principles of specimen preparation for metallography of metals apply to aluminum alloys as well. It starts with careful visual inspection of the part to be examined. Fracture surfaces must be carefully preserved against abrasions and/or contamination. If examination is being conducted for quality control, the specimen should be selected such that it represents the lot. The sectioned specimen should be properly engraved with the relevant details.

Mounting

Mounting is essential for obtaining a perfectly flat surface after polishing suitable for microscopic examination. Thin and fragile parts, such as electronic circuits, must be mounted to edge retention. Thermosetting resins are preferred over thermoplastic resins as the former yield better edge retention. Epoxy resins are widely used for a variety of reasons, as they physically adhere to specimens, and they can be drawn into cracks and pores. Specimens for anodizing can be mounted in epoxy resins with little protrusion from the back of the mount to serve as electrical contacts.

If multiple specimens are being mounted together, dissimilar materials should be avoided in a single mount as the polishing and etching characteristics are different. Cold mounting is preferred over hot mounting, if the alloy is sensitive to microstructural modifications at temperature of about 100°C.

Grinding

Grinding can be performed either manually or using automated devices. Silicon carbide has been the general choice for grinding for aluminum and its alloys. Specimens can be ground through a series of five or more sheets of SiC with increasingly finer abrasive sizes as in the conventional metallographic specimen preparation. If the damage introduced during sectioning is minimal, then grinding can start with a relatively finer grit size. Mechanical grinding is usually performed in successive steps using SiC abrasive papers of different grit sizes, 180, 220, 320, 400, 600, 800, 1000, 1200, and 2400. The starting grit depends on the type of cut surface to be removed. The surface of specimen is generally water cooled. The force for grinding should be very low to avoid deep deformation and reduce friction between grinding paper and sample surface. When polishing pure aluminum or softer tempers of aluminum alloys, grinding with heavy load for longer time can result in embedment of abrasive particles into the matrix and subsequent polishing will not be removing them. This will result in improper interpretation of the results. Further, while grinding specimens with defects such as pores and cracks, the abrasive is left in the cavities and can lead to misleading interpretations of the results in microscopy/chemical analysis using SEM-EDS. For instances where analysis of inclusions in defects (like pores or cracks) needs to be studied, serial milling of specimens using focused ion beam (FIB) attached to a scanning electron microscope (SEM) can provide accurate and reliable formation rather than conventional polishing techniques. Recently X-ray Microscopes have been emerging which enable the study of embedded defects in 3D, giving valuable morphological, structural and chemical compositional information.

Polishing

The surface scratches produced during grinding should be removed by polishing the specimen. Mechanical polishing is usually performed in two steps: initial rough polishing using 3 and 1 μm diamond paste on a short nap cloth disk followed by final polishing with a 0.25 μm diamond paste. It is important to wash the sample after the final step in an ultrasonic bath to remove the abrasive particles. In cases where polishing with 0.25 μm diamond paste does not produce a mirror-like, scratch-free surface, the final polishing can be carried out using colloidal silica or alumina suspensions. The advantage of silica over alumina is the particle size distribution, which is much narrower than

in alumina and the particles that do not agglomerate are always in suspension. This means that there is less chance of fine scratches, and it is easy to apply because it does not need continuous stirring. Another simple and easy way of obtaining scratch free surfaces is through electrolytic polishing. This technique is ideally suited for polishing pure aluminum and aluminum alloys in soft tempers that are difficult to polish mechanically. The polishing parameters viz. voltage, current and temperature for electrolytic polishing need to be optimized to obtain a mirror-like surface without any defects suitable for further etching and microscopy.

Etching

The as-polished specimen reveals a great deal of information and is useful in the case of aluminum alloys. Some phases are best identified in the as-polished condition, such as Si and Mg_2Si . Fine cracks, voids, or cracks and voids associated with intermetallic particles are easier to view in as-polished condition. However, etching of the specimen reveals the microstructure and brings in contrast to the specimen for microscopic examination. The presence of a passive film of aluminum oxide present on the surface provides good corrosion resistance makes etching difficult.^[4]

Etching is nothing but a controlled corrosion process resulting from potential difference between different microstructural features. In this process, the potential differences are exploited to produce controlled dissolution to reveal the microstructure. It may be noted that potential differences exist between differently oriented grains in pure metals and single-phase alloys, between grain boundaries and grain interiors as well as between impurity phases and the matrix or between two phases in multiphase alloys. In cases where it is difficult to etch the specimens with conventional chemical etching, electrolytic etching or anodisation can be attempted. Numerous etchants have been developed for revealing the microstructure of aluminum and its alloys. General-purpose etchants are used by swabbing or by immersion. Etching is stopped when proper degree of surface dullness is produced. The etched specimen should be washed with running water, then rinsed with ethanol, and finally dried with warm air. If multiple etchants are to be used to observe different microstructural features, the previous etched layer should be completely removed prior to subsequent etching. Table 3 presents some of the important etchants for aluminum alloys.

MICROSTRUCTURAL EVOLUTION IN ALUMINUM ALLOYS

The production of Al alloy ingots is routinely carried out by direct chill (DC), casting process. Ingots are cast by the vertical process in which the molten alloy is poured

into one or more fixed water-cooled circular or rectangular molds with retractable bases. This practice inherently introduces segregations in the cast billet and enhances the possibility of nonequilibrium reactions as solidification progresses. Figure 4 shows the macrostructure of an aluminum alloy AA2219 DC cast slab prepared to observe the possibilities of defects, if any. It can be seen from Fig. 4 that the macrostructure is free from defects such as pin hole porosities indicating that the slab is sound and suitable for further processing. The inevitable and severely cored structure of the as-cast ingot has serious consequences during subsequent downstream operations like thermomechanical processing due to presence of low melting constituents. Due to the inherently high cooling rates associated with DC casting process, the solid-state diffusion of solute within primary aluminum dendrites is not fast enough to maintain uniform distribution of solute concentration throughout the solid. This, in turn, results in a solute concentration gradient (from grain edge to grain center) across the primary aluminum grains of the solidified ingot and such grains are referred to as “cored” grains.

During solidification of ingots, both macro-segregation (involving composition variation over large distances) and micro-segregation (such as “coring” with localized composition variations) occur. It is macro-segregation that gives rise to noticeable differences in the contents of major alloying elements, such as Cu, Mg, and Zn, in the alloy before and after casting. Micro-segregations (i.e., “coring”) can be removed by proper homogenization treatment. Figure 5 shows optical photomicrographs of an aluminum alloy AA2219 processed by DC casting. The dendrites in the as-cast condition can be clearly noticed. The same alloy after addition of scandium and cast in a permanent mold reveals a completely different microstructure revealing fine equiaxed grains. The effectiveness of Zr and Sc in aluminum alloys as a potential grain refiner and recrystallization inhibitor is widely recognized.^[17,18]

Figure 6 shows the macrostructures of aluminum alloy AA2219 welds made by three different welding processes viz. tungsten inert gas welding (TIG), friction stir welding (FSW), and electron beam welding (EBW). It can be seen from these three pictures that the type of weld process determines the nature of weld macrostructure. The TIG weld is characterized by a clear and wide HAZ, the FSW by onion like weld structure and EBW by a typical narrow solidified region. The differences in the structure of weld joints and various zones formed can be clearly seen in the optical microstructure. While the fusion welded joints (TIG and EB) are characterized by solidified weld pool microstructures, the weld joint made by FSW has a thermomechanically processed ultrafine grained microstructure in the weld nugget. This example demonstrates that optical microscopy is a tool for the identification of the weld process adopted. In the present case, low-magnification pictures were obtained by stitching several

Table 3 Some of the important etchants for aluminum alloys

SI no	Etchant composition	comments
1	0.1–10 mL HF 90–100 mL water	General-purpose reagent. Attacks FeAl_3 , other constituents outlined. Grain contrast usually poor. The 0.5% concentration of HF is very popular
2	2.5 mL HNO_3 1.5 mL HCl 1.0 mL HF 95 mL water	Keller's reagent, very popular general-purpose reagent for all Al and Al alloys, except high-Si alloys. Immerse sample 10–20 s, wash in warm water. Can follow with dip in conc. HNO_3 . Outlines all common constituents, reveals grain boundaries in certain alloys
3	2.5 mL HNO_3 1.0 mL HCl 1.5 mL HF 95 mL water	Modified Keller's reagent, used on Al-Cu-Mg-Si alloys. Use as with Keller's reagent above
4	10 mL HNO_3 1.5 mL HCl 1.0 mL HF 87.5 mL water	Modified Keller's reagent. Immerse sample 15–30 s, Heat treated tempered alloy reveal high grain contrast, while artificially aged tempered alloy produce low grain contrast
5	0.5 g Sodium fluoride 1 mL HNO_3 2 mL HCl 97 mL water	Modified Keller's reagent, used to detect precipitation in age-hardened alloys. Immerse sample first in 25% aq. HNO_3 at 160°F (70°C) for 1 min and wash, and then immerse in etch for 1 min, and wash and dry
6	12.5 mL HNO_3 2.5 mL HF 85 mL water	General-purpose immersion etch
7	1–2 g NaOH 100 mL water	Commonly used etch pure Al and many Al alloys. Swab sample 5–10 s, can be heated to 122°F (50°C). Use fresh. Rinse samples in 5% aq HNO_3 . Outlines constituents except Al_3Mg_2 and (Al Cr Fe)
8	94 mL water 1 g NaOH 4 mL 0.5% aq. zinc chloride 4 mL 0.5% aq. Stannous chloride 1 g sodium carbonate	Bossert's etch for Al and Al-Cu-Mg alloys. Use fresh Immerse sample 3–5 min. Remove smut with dip in conc. HNO_3 . For annealed or cold-worked alloys
9	5 g HBF_4 200 mL H_2O	Barker's electrolytic etch to obtain grain structure of materials 30–45 V DC at 20°C. Rinse in warm water. Polarized light should be used for microscopy.
10	15 mL HF 10 mL H_3PO_4 60 mL water	Reagent for Al-Mg alloys. Produces grain contrast under polarized light.
11	2 g NaOH 5 g NaF 93 mL water	Etch for 2XXX and 7XXX wrought alloys and Al-Cu and Al-Zn cast alloys. Immerse 2–3 min. Reveals grain structure, cold working, or recrystallization
12	5 mL HF 10 mL H_2SO_4 85 mL water	Etch to study degree of recrystallization in 6XXX alloys. Immerse sample 30 s.
13	5 mL acetic acid 1 mL HNO_3 94 mL water	Etch to study degree of recrystallization in 7XXX alloys. Immerse sample 20–30 min.
14	84 mL water 15.5 mL HNO_3 0.5 mL HF 3 g CrO_3	Graff and Sargent etch for grain size of 2XXX, 3XXX, 6XXX, and 7XXX wrought alloys. Immerse sample 20–60 s with mild agitation

pictures in an image analysis software which otherwise is difficult in a conventional optical microscope. While coring can be minimized by adopting slower rates of solidification, it results in larger grain sizes and requires very long time, which is industrially uneconomical. Therefore,

thermal treatments are applied to ingots prior to hot working. These treatments, referred to as ingot preheating or homogenization, have one or more uses depending on the alloy, product, and fabricating process involved.^[19,20] The primary purpose of homogenization is to remove

Fig. 4 Macrostructure of AA2219 DC cast slab

the effects of microsegregations during casting and to dissolve the large, soluble eutectic intermetallic phases that degrade the mechanical properties of the alloy. In addition to this, homogenization is also used to precipitate fine dispersoid particles (such as Al_3Zr and Al_3Sc) that act to inhibit recrystallization during solution treatment. The maximum temperature for homogenization of alloys must be restricted to below the eutectic melting temperature, preferably 10°C – 15°C below this temperature to accommodate possible fluctuations in temperature in the furnace. The deleterious effects of exceeding the homogenization temperature are presented in Fig. 7. Figure 7a shows the optical photomicrograph of an aluminum alloy AA2014 revealing the features of eutectic melting. The rosettes indicate that the maximum permitted solution treatment temperature has been exceeded resulting in the formation of these rosettes. Figure 7b,c shows melting of grain boundaries indicating that the solution treatment temperature far exceeded the eutectic melting temperature.

Fig. 8 shows the details of electron probe microanalysis (EPMA) conducted on aluminum alloy AA7075 in two different conditions viz. in as-cast and homogenized condition and in as forged and solution-treated condition. The variation of elements (Zn, Cu, Fe, Mn, Cr, Zr, Si, and Mg) present in AA7075 of the microstructure is also presented. It can be seen that even after homogenization of the as-cast ingot, elemental variations are present in the

material. However, after thermomechanical processing followed by a solution heat treatment step, the compositional variation has been nullified. EPMA is a powerful tool in analyzing the chemical composition of various individual phases present, their variation across the grain boundaries, and to determine the local segregation of alloying additions and it is regularly used in the research and development of advanced aluminum alloys. During wrought alloy production, the processing steps usually follow melting; casting homogenization; scalping; thermomechanical process to produce various product forms, such as forgings/plates/sheets/extrusions; solution treatment; quenching; cold stretching for extrusions and flat products or cold compression for forgings; and finally artificial aging. The selection of suitable homogenization cycle is necessary to eliminate low-melting phase mixtures and dendritic segregation typically observed in as-cast microstructure and to facilitate uniform distribution of the dispersoids. Almost all commercial aluminum alloys contain dispersoid forming elements such as Cr, Mn, Zr, or Sc. These elements form compounds with Al and other alloying elements, e.g., $\text{Al}_{12}\text{Mg}_2\text{Cr}$, $\text{Al}_{20}\text{Cu}_2\text{Mn}_3$, Al_3Zr , and Al_3Sc . These dispersoids form during homogenization inhibit grain growth and recrystallization during thermal and mechanical processing of these alloys. The homogenized billets are then hot worked to obtain semi products such as forgings, plates, or extrusions.^[21–23] These products are solution treated and water quenched. Cold stretching (for extrusions and plates termed TX51) and cold compression (for forgings termed TX52) are carried out immediately after quenching to relieve from the quenched-in stresses.

Wrought compositions that do not respond to strengthening by heat treatment include grades of pure aluminum (1XXX series) as well as alloys with Mn (3XXX series) or Mg (5XXX series) as major additions, either alone or in combination. A significant percentage of all aluminum flat rolled products are made from these three non-heat-treatable alloy groups. In these alloys, strength

Fig. 5 Optical photomicrographs of aluminum alloy AA2219 (a) DC cast taken from the periphery of the ingot and (b) modified with scandium in a permanent mold

Fig. 6 Macrostructure of aluminum alloy AA2219 welds made by three different weld processes viz. TIG, FSW, and EBW. Note the differences in the structure of weld joints and various zones formed. Low-magnification pictures are obtained by stitching several pictures in an image analysis software

is developed by strain hardening, usually by cold working, in association with solid solution hardening (Al-Mg) and/or dispersion hardening (Al-Mn/Al-Mn-Mg). Applications of super purity and commercial purity aluminum (1XXX series) include electrical conductors, chemical process equipment, foil and architectural purposes requiring decorative finishes. The 3XXX series of alloys are used when moderate strength combined with high ductility and excellent corrosion resistance are required. Al-Mg alloys are widely used for welded constructions.

The inevitable presence of Fe and Si in aluminum reduces the fracture toughness by precipitating as aluminides of iron and silicon. The presence of both these alloying elements increases the solidification range. Reducing the amount of Fe and Si reduces the amount of eutectic precipitates along the grain boundaries. It is much easier for cracks to be initiated along the grain boundaries, when the eutectic precipitates are present. Therefore, it is essential to reduce the amount of precipitates along the grain boundaries that results in improved mechanical

properties of the weld joints, particularly impact strength and ductility. Further, these impurities affect the quality of chemical milling of commercial aluminum alloys drastically.

Varying degrees of changes occur to the as-cast aluminum alloy ingots microstructure depending on the nature and amount of deformation introduced. While changes are minimal in heavy forgings, thick plates, and large diameter extrusions, they become prominent as the degree of reduction with respect to original cross-sectional area is high. Aluminum alloys retain their grain shape even after solution treatment, and highly elongated grains can be observed in thin sheets, extrusions, and ring-rolled rings. Figure 9 shows the optical photomicrographs of aluminum alloy AA2014 in different product forms starting from the DC cast stage to different product forms as the thermomechanical processing steps progress viz. hot forging, hot rolling, cold rolling, extrusion, and riveting operation. The evolution of microstructure from the DC cast stage can be clearly seen with respect to the grain shape, size,

Fig. 7 Optical photomicrograph showing (a) features of eutectic melting in AA2014 indicating that the solution treatment temperature has been exceeded, (b) melting of grain boundaries indicating that the solution treatment temperature far exceeded the eutectic melting temperature, and (c) same as (b) taken at higher magnification

and orientation. As the deformation proceeds, the grains get more flattened and oriented in the direction of metal working. This has inherent bearing on the mechanical properties of the material.

The initial size of second-phase particles formed during solidification depends on the rate of heat removal. The degree of size reduction and their distribution in the matrix depends on the amount of deformation the material has undergone. The amount of excess soluble phase depends on the individual heat within the specification limits of the alloy and the thermal treatment undergone. The quantity, size, and distribution of dispersoids depend on the composition of the alloy and the nature of thermomechanical processing history the material has undergone. Similarly, the degree of recovery/recrystallization, size, and shape of recrystallized grains depend on these factors. A detailed understanding of the interaction of the above variables is essential for correct interpretation of the microstructural features in a given alloy and product. Therefore, the microstructure gradually gets refined as the original ingot structure is broken down during subsequent thermomechanical processing treatments into forgings, plates, sheets thus

removing directionality in mechanical properties. Simultaneously, the second-phase particles also get broken down in size and get uniformly distributed in the matrix. The limited extent of thermomechanical processing in large-sized forgings thick plates and large diameter ring-rolled rings leaves coarse and undistributed second-phase particles and their effect on the mechanical properties need to be ascertained for the intended applications.

MICROSTRUCTURAL FEATURES OF VARIOUS ALUMINUM ALLOYS

Wrought aluminum alloys are divided into seven major classes depending on the principal alloying additions to pure aluminum. These classes can also be divided based on the nature of strengthening such as those which can be strengthened only by work hardening (1XXX, 3XXX, 4XXX, and 5XXX series of alloys) and those by precipitation hardening (2XXX, 6XXX, 7XXX, and 8XXX series). Each alloy class exhibits a different type of microstructure right from the as-cast ingot to various

Fig. 8 EPMA of aluminum alloy AA7075 showing the elemental distribution in (a) as-cast and homogenized condition and (b) forged and solution treated condition

product forms.^[24,25] Typical microstructural features for each class of alloy are presented in the “*Atlas of Microstructures*” as an annexure to this book which reveal how the as-cast microstructure progressively develops into final wrought forms.

1XXX series alloys (>99% Aluminum): 1XXX series aluminum alloys are commercially pure aluminum. They are not heat treatable. The characteristics of these alloys are as follows: (a) very low strength as there are fewer solutes resulting in fewer barriers against dislocation mobility facilitating very high formability and workability, (b) improved corrosion resistance as there are almost no intermetallics, (c) high thermal and electrical conductivities as the impurity levels are low, and (d) reflective and decorative that is an inherent feature of pure aluminum. The combination of these properties makes these alloys very attractive for packaging (formable household foil and food containers), electronic devices (high conductivity electrical cables), heating equipment (heat exchanger strip and radiator tubes), lighting applications (reflector casings), and decoration (high reflectivity and aesthetic appeal for furniture fittings). Because the solid solubility of iron and silicon is low, intermetallics of iron and silicon precipitate out of solution in these alloys, and the typical compositions of the phases present in these alloys

are FeAl_3 , $\text{Fe}_3\text{SiAl}_{12}$, or $\text{Fe}_2\text{Si}_2\text{Al}_9$. Factors governing phase selection in 1XXX series aluminum alloys containing iron and silicon can be found elsewhere.^[26]

The electrical conductivity of aluminum and its alloys is generally reduced due to the presence of impurities such as silicon. The control of the content and morphology of Si is a key factor to produce high-quality aluminum conductors. Utilization of iron to control the harmful effect of silicon has been attempted.^[5] The electrical conductivity of dilute Al–Si alloy can be improved with the addition of Fe, and the ultimate tensile strength and electrical conductivity of Al–Fe–Si alloys can be further improved by homogenization. It is attributed to the formation of $\alpha\text{-Al}_8\text{Fe}_2\text{Si}$ ternary eutectic phase.

2XXX series alloys (Al–Cu): Alloys of this class are usually complex because of the many alloying additions (such as Mg and Mn) used for strength, corrosion resistance, and for control of grain structure. The addition of copper as main alloying element (mostly range 3–6 wt%, but can be much higher), with or without magnesium (range 0%–2%), allows material strengthening by precipitation hardening. Alloys of this class are used for variety of applications like interstage rings (2014) and propellant tanks (AA2219) of satellite launch vehicles. Copper is the primary alloying addition and is present in the alloys as

Fig. 9 Optical photomicrographs of aluminum alloy AA2014 showing (a) as DC cast and homogenized, (b) forging in T652 condition, (c) 25 mm thick plate in T651 condition, (d) clad 0.8 mm thick sheet in T6 condition, (e) extrusion in T6511 condition, and (f) head to shank region in a forged head of a rivet

Al_2CuMg (in the presence of Mg such as AA2014) and CuAl_2 (as in AA2219). These alloys need heat treatments viz. solution treatment followed by aging to improve their strength. Because solution treatment temperature is close to equilibrium solidus temperature, overheating is a hazard that needs microscopic examination. The first stage of overheating is the appearance of “*Rosettes*” which is the melting of the undissolved eutectics and is termed “*eutectic melting*”. Rosettes appear as the quenching operation is conducted while the liquid is still present. Further overheating causes grain boundary melting particularly at triple junctions. Contrast in microstructure of copper containing

2XXX series alloys is obtained due to the combination of etch pitting and redeposition of copper on more rapidly dissolved grain orientations.

Commercial AA2024 in T4 condition shows Al_2CuMg as an undissolved excess phase and irregularly shaped particles of unreacted $(\text{Mn,Fe})\text{SiAl}_{12}$ and reacted $\text{Al}_7\text{Cu}_2\text{Fe}$ together with dispersoids of $\text{Cu}_2\text{Mn}_3\text{Al}_{20}$. In contrast with AA2024, the alloy AA2014 has lower Mg content and higher Si. The higher silicon stabilizes $(\text{Mn,Fe})\text{SiAl}_{12}$ as the only iron-rich phase. The soluble phases are CuAl_2 and $\text{Cu}_2\text{Mg}_8\text{Si}_6\text{Al}_5$, and another dispersoid $\text{Mn}_3\text{SiAl}_{12}$ also exists along with $\text{Cu}_2\text{Mn}_3\text{Al}_{20}$. The higher dispersoid

concentration and pronounced banding inherited from the cast stage result in a recrystallized grain structure of highly elongated grains in sheets.^[27–29]

In aluminum alloy AA2219 (Al-Cu-Zr-V-Mn-Ti alloy), Cu is in the range of 5.8–6.8 wt% i.e., beyond the maximum solid solubility of 5.7 wt% of Cu in aluminum. The high percentage of Cu results in the improvement of the weldability of the alloy by increasing the total volume of the eutectic liquid available to heal solidification cracks. The purpose of minor alloying elements, such as Zr, V, Mn, and Ti, is to refine the weld metal grain size.

It may be noted that the presence of both Cu and Mg as major alloying elements in an Al alloy makes it non-weldable. This is related to the reduction in the total volume of the eutectic liquid that is required to heal the solidification cracks together with the formation of low-melting phase mixtures of undesirable morphology at the grain boundaries. It may be noted that 3xxx, 5xxx, and 6xxx series Al alloys are weldable, whereas 2xxx and 7xxx series alloys containing both Cu and Mg as major alloying elements are non-weldable. However, by suitable techniques, these alloys can still be welded to obtain sound joints by fusion welding.

3XXX series alloys (Al-Mn): Manganese is the main alloying element in the 3xxx series (range 1–2 wt%) aluminum alloys. Alloys of this series have medium strength, are ductile, and have good formability. These alloys can be tempered to obtain a wide range of mechanical properties through strain hardening. Dispersoids present in these alloys stabilize grain size during annealing, thereby improving strength and formability. A typical application is the “beverage can” body due to the alloys’ good formability by pressing, roll forming, and drawing. During homogenization of DC cast ingots of Al alloys for beverage-can bodies, the degree of transformation of $Al_6(Fe,Mn)$ phase to α -Al-(Fe,Mn)-Si phase is important for subsequent processing.^[30] These alloys are also used for their good combination of strength, formability, weldability, anodization behavior, and corrosion resistance in packaging, architectural, and home appliances. The most popular alloy in this group is AA3003 with the dominant phases $(Mn,Fe)Al_6$ and $(Fe,Mn)_3SiAl_{12}$. Manganese supersaturates the cored solid solution of the primary dendrites and subsequently precipitates as dispersoids.

4XXX series alloys (Al-Si): Alloys of this series are low ductile in nature due to high silicon content (up to 12 wt%). These alloys have very low formability. They find only a limited number of applications as wrought products. Most of the wrought 4XXX series alloys are used as welding and brazing filler materials except for some forged pistons and architectural applications. In the case of fillers, they are remelted and the as-cast microstructure usually has elemental silicon and $Fe_2Si_2Al_9$. Thermal treatments cause silicon to coalesce and spheroidise. The iron-rich precipitates are seen as needles. AA4043 is used as welding filler wire. Aluminum-silicon alloys containing high

levels of Si are extensively used in the foundry industry due to their high fluidity during casting.

5XXX series alloys (Al-Mg): The addition of magnesium as an alloying element to aluminum (used up to 6 wt%) imparts solute hardening to the alloy coupled with efficient strain hardening. These alloys are generally stronger than the medium strength 3xxx series alloys and also possess very good formability. These alloys are non-heat-treatable, but are readily welded and show good corrosion resistance. These alloys are used as welded constructions for containing liquid fuels of rockets. The primary alloying element is Mg that shows a high solubility in aluminum. When the magnesium content is greater than 3.5%, the excess magnesium precipitates out as Mg_5Al_8 . Cold working of aluminum-magnesium alloys produces prominent deformation bands. The combination of good formability, medium strength, good corrosion resistance, and weldability results in many applications such as in building architecture sheet, ship building, and automotive applications.

6XXX series alloys (Al-Mg-Si): These alloys containing Mg and Si are readily heat treatable and show good quench sensitivity. It is necessary to control the processes of dispersoid and precipitate formation so as to obtain the desired strength, grain size, and crystallographic texture in the materials. These alloys also offer a low solution-treated strength for high formability, combined with rapid age hardening to a relatively high strength in the formed component during the paint bake cycle for automotive applications.^[31] If the volume fractions of Mg and Si are low (such as in AA6063), then the Mg_2Si can be completely dissolved during the solution treatment and can be precipitated out subsequently. On the other hand, if Mg and Si are in excess (such as AA6061), the excess Mg_2Si forms a distinct widmanstatten pattern. The medium strength 6XXX series alloys, on the other hand, are used in a wide range of structural products, largely as extruded shapes. Al-Mg-Si alloys have the advantages of good weldability, corrosion resistance, and immunity to stress corrosion cracking (SCC). These alloys are used for water tanks in liquid engines of satellite launch vehicles, as extrusions in engineering components, in construction, and automotive applications.^[32–36]

7XXX series alloys (Al-Zn-Mg-(Cu)): This class of alloys contains zinc, magnesium, and copper as principle alloying additions as well as additives such as chromium, manganese, zirconium, and the ever-present iron and silicon. Both copper containing (like AA7075) and non-copper containing (like AFNOR 7020) aluminum alloys are widely used in aerospace structures for a variety of applications ranging from forgings to propellant tanks. This system offers the best combination of strength and fracture toughness. These alloys are readily heat treatable. The equilibrium phases in Al-Mg-Zn are $MgZn_2$ (η), $Mg_3Zn_3Al_2$ (T), and Mg_5Al_3 (β). If the quantity of Zn is more than Mg, then precipitation sequence to $MgZn_2$ is predominant. If Mg is

more than Zn, then $\text{Mg}_3\text{Zn}_3\text{Al}_2$ (T) phase is predominant. If Cu is added and is more than Mg, Al_2CuMg (S) phase is dominant. The presence of chromium results in fine dispersoids that hinder recrystallization during hot working. Other dispersoids like Zr and Sc are also used to increase the recrystallization temperature.^[37]

Alloy AA7075 in the as-cast condition forms $(\text{Fe,Cr})_3\text{SiAl}_{12}$, Mg_2Si and a pseudo-binary eutectic of aluminum, and MgZn_2 . Subsequent heating causes the iron-rich phases to transform to $\text{Al}_7\text{Cu}_2\text{Fe}$. Mg_2Si is relatively insoluble and tends to spheroidize. $\text{Mg}(\text{Zn,Cu,Al})_2$ rapidly begins to dissolve and simultaneously Al_2CuMg precipitates which requires high temperatures and long soaking times to become completely dissolved. $\text{Cr}_2\text{Mg}_3\text{Al}_{18}$ is precipitated from supersaturated solid solution and gets concentrated heavily in the primary dendrite regions. After solution treatment, the wrought alloy contains $\text{Al}_7\text{Cu}_2\text{Fe}$, $(\text{Fe,Cr})_3\text{SiAl}_{12}$ and Mg_2Si along with the dispersoids. The dispersoids get aligned in the direction of thermomechanical processing and the recrystallised grains are highly flattened and elongated. The unrecrystallized regions in hot worked products are made up of fine sub grains with strengthening precipitates decorating the grain boundaries. Aluminum alloys, encompassed by AA 7055 alloy composition, having the nominal zinc content (i.e., 8 wt%) but varying copper and magnesium contents across the alloy composition range were observed to contain second phases based on $\eta(\text{MgZn}_2)$, $\text{T}(\text{Al}_2\text{Mg}_3\text{Zn}_3)$, and $\text{S}(\text{Al}_2\text{CuMg})$.^[38]

MICROSTRUCTURAL EVALUATION OF COMMERCIAL ALUMINUM ALLOYS

The chemistry of various intermetallics phases present in aluminum alloys is well established, and their examination can be easily conducted in an optical microscope by identifying their optical characteristics such as color and contrast and etching. The chemical composition of these intermetallics phases can be confirmed in specimens in as-polished condition in a SEM fitted with an EDS. However, in practice, it is very difficult to obtain the same location in the SEM of a region observed in optical microscopy. To overcome this difficulty, "correlative microscopy" is useful under such circumstances. For this purpose, a correlative stage is used for fixing the coordinates of a feature in an optical microscope and the stage is transferred to an SEM for precisely pinpointing the location observed in SEM. This is extremely useful in precisely identifying features in a complex alloy where a number of phases are present.

Figure 10 shows the optical photomicrographs in as-polished conditions showing various phases in different contrast in aluminum alloy AA7075-T6 (a and b), MSRR8009 (c) and A380 (d) in cast and heat-treated condition. It can be seen from these figures that the orientation, shape, size, and distribution of second-phase particles can

be clearly studied from the micrographs in the as-polished condition. In light optical microscopy, various phases/compounds have different colors and contrast that will help in routine analysis of materials. Observation in the as-polished condition will facilitate better understanding of the presence of second phases present, since etching of the material camouflages these finer details, highlighting the grain structure.

Figure 11a shows the photomicrograph of an aluminum alloy AA2014 in as-polished condition taken in a SEM along with the energy dispersive spectrum of a particle to determine the composition. Figure 11b shows the photograph and EDS spectrum of zirconium segregation in an aluminum alloy along with X-ray maps of zirconium and aluminum. Zirconium is added to aluminum alloys in the form of Al-Zr master alloy and is supposed to be uniformly distributed. In the present case, Zr segregation was noticed that makes some areas devoid of this important addition.

In Al-Cu-Li alloys, Cu is the principal alloying element and Lithium is the second major alloying element. θ' is the major phase in constituent binary Al-Cu system. Lithium, when present in small amounts, encourages the formation of a ternary phase T1 (Al_2CuLi). Figure 12 shows transmission electron micrographs of aluminum-copper-lithium alloy AA2195 in T87 condition. At low magnifications (a) the grain structure can be seen, whereas at high magnifications (b and c) the presence of precipitates of CuAl_2 and T1 are revealed. Figure 12d shows a high resolution TEM micrograph of T1 precipitate. These precipitates are submicroscopic and need TEM for resolving them.^[39-42]

NONDESTRUCTIVE IN SITU METALLOGRAPHY

The conventional metallographic procedures involve specimen preparation by polishing the surface of the intended material and chemical etching to reveal the microstructures in the laboratory. This technique is destructive; hence, it has its own limitations for large-sized fabricated products due to the inherent value added during their manufacture. Non-destructive metallography is a technique which offers solutions to this problem and has emerged as a routine and important tool in the hands of metallurgists. In this technique, the microstructure of the component in the field/service can be observed without affecting its subsequent functional usage. This involves local preparation of the component followed by replication and its observation under microscope. The results obtained are comparable to those obtained through conventional metallographic practices and therefore is practiced extensively.

Non-destructive metallography is widely used to evaluate the heat treatment condition of materials, effect of thermal conditions, and assess the microstructural changes of the component during its lifetime specially for assessing the creep-damage at elevated temperatures.

Fig. 10 Optical photomicrographs in as-polished condition showing (a and b) various phases with different contrast in AA7075-T6, (c) MSRR8009, and (d) A380 in cast and heat treated condition

It is also used as a quality control tool during processing of materials. Failure analysis of large-sized components to assess the nature of discontinuities, cracks, and material damage like pitting are other common examples where non-destructive metallography is useful.

High-strength aluminum alloy AA7075 forgings are used for the fabrication of control components in liquid engines of the satellite launch vehicles. In situ metallographic characterization was carried out on the forged block (Fig. 13a) of the AA7075 alloy and finished component (Fig. 13b) to evaluate the microstructural features. Replicas were taken and were observed in an optical microscope. Observations of the replicated microstructure in the optical microscope revealed dendritic coring at the core and middle locations on the radial plane. Periphery of the forging revealed a worked structure with elongated grains.

SUMMARY

Metallography is the science of studying the microstructure of materials. Obtaining a good microstructure is an art in itself. With automated polishing machines readily

available and with the number of recipes that come with them supported by customized and patented consumables, it has become easier to obtain scratch free surfaces suitable for optical metallographic examination. Years of experience with meticulous preparation methods are still in vogue for difficult to polish materials, one such examples being superpure aluminum. With variety of etchants for macro- and microetching of aluminum alloys to reveal different features, it is a metallurgical paradise for metallographers to observe microstructures of various aluminum alloys unprecedented and unrivaled by any other alloy system.

Care must be taken to avoid embedding of any extraneous materials into aluminum alloys in the softer tempers. Observation in unpolished condition will reveal many interesting features that get camouflaged with etching. Selection of suitable etchant to delineate the desired feature is important. If multiple features are required to be observed and recorded, the previous etching layer needs to be fully removed.

Microstructure reveals more than what meets the eye. Therefore, careful and unbiased examination of the specimen is essential to get correct information about the material. This is particularly important in recording pictures

Fig. 11 Photomicrograph of (a) an aluminum alloy AA2014 polished specimen taken in a SEM along with the energy dispersive spectrum of a particle to determine the composition and (b) photograph and EDS spectrum showing Zirconium segregation in an aluminum alloy with X-ray mapping of Zirconium (left) and aluminum (right)

of two-phase alloys, composites, weld structures, and specimens involved in failure analysis where one tends to observe, highlight, and take selective pictures suiting the expectations or theory in mind. This can result in the loss of important and useful information in being captured.

Aluminum alloys are complex in the sense that along with the alloying additions, there are deliberate minor

additions like Cr, Mn, and Zr along with undesirable but unavoidable elements like Fe and Si, and other impurities. This is further complicated by a large number of temper conditions available for various alloys and product forms. The microstructures and sub-microstructures present a gamut of information to the physical metallurgist that can help him decipher the secrets of interplay between

Fig. 12 Transmission electron micrographs of aluminum-copper-lithium alloy AA2195-T87 condition showing (a) low magnification photograph (b) high magnification picture of the same location showing precipitates of CuAl_2 and T1 (c) T1 phase, and (d) high resolution micrograph of T_1 precipitate

the alloying additions and effects of thermomechanical processing. Proper analytical tools need to be used for obtaining the required information for the analysis.

In the case of failure analysis investigations, extreme caution has to be exercised while cutting the specimen in order to avoid external damage to the component. It is all more important to record the necessary information before sectioning, and the parts sectioned in big components may be suitably numbered so that the specimen or defect orientations can be traced back to the original component, if required. Utmost care should be taken to preserve the fracture surfaces. Every failure leaves a “finger print” that needs to be identified through the microstructural examination of the component. Nondestructive metallography is a very important tool in decision-making in cases where significant value addition has been made to a component about its usability or where it is mandatory as a part of quality control

procedures such as degradation of materials through the evaluation of microstructure of power plants components.

ACKNOWLEDGMENTS

The authors wish to thank their colleagues in Material Characterisation Division for their excellent support in the preparation of this article. They wish to thank the group members of Materials and Metallurgy Group for their constant support. They profusely thank all the members of the Materials and Mechanical Entity who have directly or indirectly contributed to this work. They thank Group Director, MMG for his constant encouragement and Deputy Director, Materials and Mechanical Entity for his support in all their activities. They wish to thank Director, VSSC for his permission to publish this work.

In spite of a strong commercial interest in hot dipped aluminised steel strip, research over the past 60 years has been somewhat piecemeal. A relatively smaller body of work exists on this material compared with the equivalent galvanised product but the lack of systematic study and development means that it is difficult to rationalise and appraise the existing literature. This review is intended to provide an overall view of the salient results of previous work, providing key entry points to available literature.

INTRODUCTION

The coating of steel with aluminium is an economical means of combining the corrosion resistance of aluminium with the strength of steel. The coating operation can be performed by a variety of processes,^[1–3] but continuous hot dipping of wide steel strip remains the most economical for the mass production of aluminised steel.

World production of hot dipped aluminised strip was estimated in the 1980s to be well in excess of 1 Mt/year^[4,5] since when there has been some increase in world production capacity. Currently, aluminised steels probably account for about 5% of total world production of all hot dipped coated steels.

Commercially, there are generally two different grades of hot dipped aluminised steel (hot dip aluminised steel).^[6] Type 1 hot dip aluminised steel comprises a steel substrate coated with an Al–Si alloy of near eutectic composition (~11 wt-%Si*). Generally, this material is used in a variety of applications where resistance to both corrosion and elevated temperature oxidation is required. Typical examples include motor vehicle exhaust systems

and domestic appliances such as cookers, dryers, and heating boilers, etc. Type 2 hot dip aluminised steel consists of a steel substrate coated with commercially pure aluminium. This material generally only finds applications where resistance to ambient temperature corrosion is required, usually in conjunction with a demand for a high reflectivity surface. The main market for this material is in the construction industry, typical examples being building cladding panels and air conditioning and/or ventilation systems.

Type 2 aluminised steel is commercially produced with standard minimum coating weights^[6,7] of 195 and 305 g m⁻² (approximately equivalent to coating thicknesses of 38 and 60 µm, respectively); analogous values for the Type 1 grade are 75 and 120 g m⁻² (15 and 25 µm, respectively). In recent years hot dip aluminised steel specifications and application patterns have become somewhat indistinct. In the UK, for example, the only indigenous producer of hot dip aluminised steel^[8] exclusively manufactures the Type 1 grade for both heat resistance and ambient temperature applications. The latter product is designated Type 1 ‘Building quality’ and has a minimum 45 µm coating thickness. A similar ‘non-standard’ product is a 40 g m⁻² (~ 8 µm coating thickness) grade. Analogous products in Japan have led to the development of specifications which differentiate

*All compositions are given in weight-% unless otherwise stated.

aluminised steels on the basis of coating thicknesses rather than coating composition.

Historically, Type 2 hot dip aluminised steel has commanded only a very small proportion of the European coated sheet steel market. A relatively larger market has traditionally existed for the Type 2 material in the USA where it directly competes with galvanised and the newer Zn–Al alloy hot dipped coated sheet steels such as Galvalume™ and Galfan™.[†]

Although these latter grades of material pose a special threat to traditional hot dip aluminised steel markets, the advantages stemming from the unique properties of aluminised steels are widely recognised, their use continuing to increase despite their somewhat higher production costs. Currently (1994), approximate cost comparisons for equivalent width and gauge materials are typically £491/t for hot dip galvanised sheet and £559/t for Type 1 hot dip aluminised sheet; Zn–Al coated sheet falls roughly between the two.^[8] Despite the disparity in cost, hot dip aluminised steel has the advantages of combining good corrosion and oxidation resistance with exceptional heat and light reflectivity properties: neither hot dipped galvanised steels nor Zn–Al hot dipped coated steels can match this particular combination of properties.

In relation to market viability, the production of ‘enhanced’ grades of the Type 1 material is especially significant. These have substrates modified to improve elevated temperature performance, with several grades having properties claimed to be on a par with those of cheaper grades of stainless steel.^[9,10]

The manufacture of hot dip aluminised steels involves immersion of suitably processed steel strip in a bath of either the Type 1 or Type 2 molten coating medium. In the bath, reaction diffusion proceeds between the iron of the steel and the aluminium or Al–Si melt. This results in the formation of a layer of hard brittle Fe–Al or Fe–Al–Si intermetallic compounds colloquially termed the ‘alloy layer’. On withdrawal from the melt, a thin film of liquid coating adheres to, and subsequently solidifies on, the alloy layer. In effect, the alloy layer metallurgically bonds the outer lustrous coating to the underlying steel substrate.

All industrial hot dip coating processes must of necessity provide efficient predip strip cleaning in order that wetting by, and reaction with, the liquid coating medium can occur. Also, the process must enable strict control of the coating reaction, namely, control the rate of alloy layer growth during dipping. This last factor is imperative since the extreme brittleness of the intermetallic compounds of the alloy layer means that the thickness of this

layer is the major influence on successful post-dip forming operations: too thick an alloy layer leads to coating cracking and delamination on subsequent fabrication of the material.^[11] The main influences on the rate of alloy layer growth during aluminising are dip time, dip temperature, and bath composition. All three factors are amenable to direct control during production. The influence of steel composition is also important but this cannot at present be materially changed or controlled on the aluminising line: the effect of steel composition variations on alloy layer growth rate can only be adjusted for by varying the three process variables listed above.

Practically all continuous hot dip aluminising of wide steel strip is nowadays performed on ‘Sendzimir type’ continuous coating lines modifying a technology originally patented for the continuous production of hot dipped galvanised strip.^[12] The literature contains many general descriptions of this type of continuous aluminising line^[13–18] though specific plant designs and operating details are usually regarded as commercially sensitive information.

Fundamentally, the modified ‘Sendzimir type’ process involves strip preheating in controlled atmospheres to remove surface organic contaminants and surface oxides. This is achieved by passage through non-oxidising and reducing furnaces operated in tandem at 500 and 850°C, respectively. This heating stage also imparts an annealing cycle to the strip following cold reduction. After online heating, the strip enters the dipping bath at a temperature closely matching that of the melt. Type 1 dipping is performed at about 670–700°C, with Type 2 dipping at about 700–730°C. Dipping time and line speed are specific operating parameters optimised for efficient strip heating and surface cleaning and, also, minimisation of alloy layer growth on passage of the strip through the melt. Typical dipping times are of the order of 4–8 s with modern lines operating at speeds in excess of 175 m min^{−1}. On emerging from the melt, the excess liquid coating adhering to the alloy layer is forced back into the melt by blasting from ‘gas knives’.^[19,20] This system, in conjunction with continuous online X-ray coating thickness measuring equipment, enables precise control of the outer deposit of coating on the alloy layer. Subsequent solidification of this surface liquid coating, together with finishing treatments such as temper passing, roller levelling, and chromating and/or oiling complete the manufacturing process.

Alternative continuous hot dip aluminising processes, such as the Cook–Nortemann process^[21,22] are generally termed ‘cold line’ methods.^[13] These rely on predip strip cleaning by chemical means and usually employ aqueous alkaline degreasing, acid pickling, and a final fluxing of the strip before hot dipping to prevent reoxidation of the surface. A variety of fluxes can be employed including aqueous halide solutions or organic liquids such as linseed oil or glycerol. Alternatively, molten halide fluxes can be used, or fluxes dispensed with completely and a flash electrolytic deposit of copper applied to the sheet surface.^[3,17,18,23–27]

[†]Galvalume is 43.5Zn–55Al–1.5Si alloy hot dip coating system developed and marketed by the Bethlehem Steel Corp., USA. Galfan is an approximately 95Zn–5Al hot dip coating system developed and licensed under the auspices of the International Lead Zinc Research Organisation, USA.

Since they do not incorporate an heating-annealing stage, cold line methods demand fully annealed strip feedstock. These methods continue to find limited application as an alternative to the more expensive and sophisticated technology of the Sendzimir type process.^[23–25]

STRUCTURE OF HOT DIP ALUMINISED COATINGS

Phase Equilibria Systems Relevant to Hot Dip Aluminising

Before discussing the structure of hot dipped aluminised steels, it is appropriate to review information on the Fe–Al, Al–Si, and Fe–Al–Si phase equilibrium systems.

Fe–Al System

Discussions of this equilibrium system and phase crystallography are provided in Refs. [28–38]. Table 1 gives a summary of phase information relevant to hot dip aluminising in the temperature range 670–730°C. A simplified phase equilibrium diagram is shown in Fig. 1. Reference to Table 1 shows that in the range 0–34wt-%Al, there exist a range of solid solution phases based on the bcc lattice of α -Fe. Much uncertainty exists as to the precise equilibrium stability of these phases despite numerous investigations.

With increasing aluminium concentration in the range 34–62 wt-%Al, three distinct Fe–Al intermetallic compounds, ζ -FeAl₂, η -FeAl₅, and θ -FeAl₃ are evident. The crystallographic structures and homogeneity ranges of these compounds are also detailed in Table 1. Original crystallographic data for the ζ -FeAl₂ phase was obtained by Osawa,^[39] who deduced a rhombohedral structure. This

Fig. 1 Fe–Al phase equilibrium system^[28]

data was re-interpreted by Bradley and Taylor,^[40] who suggested that the original deduction was incorrect and that the complexity of the data inferred a monoclinic structure. Pearson^[35] argues that much uncertainty remains. A more recent study by Meyer and Morandini^[41] has not clarified the issue satisfactorily.

Table 1 Fe–Al system phases^{[29]*}

Phase	Stoichiometry	Crystal structure
α -FeAl	...	bcc
β_1	Fe ₃ Al	Cubic (BiF ₃ -type)
β_2	FeAl	Disordered, bcc
β_2	FeAl	Ordered, bcc
ζ	FeAl ₂ (47–50 wt-%)	Monoclinic, (rhombohedral?)
η	Fe ₂ Al ₅ (52–54 wt-%)	Orthorhombic
θ	FeAl ₃ (57–62 wt-%)	Monoclinic
Al–Fe	...	fcc
Solubility of Fe in Al		
700°C ~ 2.5 wt-%		
600°C ~ <0.1 wt-%		

* ϵ -Fe₂Al₃ (complex cubic, bcc) not relevant to hot dip aluminising (high temperature phase).

FeAl₆ (monoclinic) metastable phase.

Fe₂Al₇ (reported as rhombohedral) – no recent evidence to substantiate existence.

Similar original deductions on the structure of the η -Fe₂Al₃ phase by Osawa^[39] have been superseded by detailed analyses^[42,43] which showed an orthorhombic structure. Special attention must be paid to this later study which showed the *c*-axis of the orthorhombic structure to consist entirely of aluminium atoms about 30% of which are absent. This observation probably accounts for the extremely rapid growth and directionality of this phase in aluminising. Interestingly, in hot dip galvanising, η -Fe₂Al₃ formation has been implicated in the inhibition of Fe–Zn reaction diffusion even when aluminium is present in the zinc melt at relatively low concentrations.^[44,45]

The third intermetallic phase in this range is θ -FeAl₃, originally believed to be orthorhombic,^[46,47] but subsequently shown to be monoclinic.^[48] Three other Fe–Al intermetallic phases merit mention. Most Soviet and several other studies cite an Fe₂Al phase.^[39,40,46,49] Bradley and Taylor^[40] suggested this phase was produced on decomposition of θ -FeAl₃ at about 558°C, and was accompanied by formation of η -Fe₂Al₃. This has been strongly refuted by Pearson,^[35] Black,^[48] and Raynor and Pfeil,^[50] these workers attributing its existence to spurious observations. There is, however, agreement on the existence of an FeAl₆ phase which is metastable in the Fe–Al system.^[51–55] The ϵ -Fe₂Al₃ phase, which forms above 1092°C, is not relevant to hot dip aluminising.^[48]

At the aluminium rich end of the Fe–Al system a eutectic exists at 652°C between θ -FeAl₃ and the very dilute primary Al–Fe solid solution. The composition of the eutectic probably falls in the range 1.7–2.2 wt-%Fe;^[30] this uncertainty arising from phase nucleation difficulties which favour a divorced eutectic. The equilibrium solubility of iron in aluminium is quoted as very small at less than 0.1 wt-%Fe at 600°C.^[29]

Al–Si System

This system is a simple eutectic at 11.7 wt-%Si between primary Al–Si solid solution and silicon.^[28] The solubility of silicon in aluminium reaches a maximum at 1.65 wt-%Si at 577°C.^[34] Data for the solubility of aluminium in silicon are controversial but most determinations put the figure at less than 0.1 wt-%Al at the eutectic temperature of 577°C.^[34,36]

Fe–Al–Si System

Information on phase relations in the Fe–Al–Si system relevant to hot dip aluminised steels is very sparse. Apart from a dated general study by Takeda and Mutazaki,^[56] other more limited work has concentrated almost exclusively on aluminium rich Fe–Al–Si alloys.^[2,46,48,57–67]

Mondolfo^[30] provides a detailed review of most published information on this system to 1975. He asserts that only two ternary phases can exist in equilibrium with aluminium: α -Fe₂SiAl₈ and β -FeSiAl₅. He further suggests that another phase δ -FeSi₂Al₅ is often present in high silicon alloys, and, that a fourth phase, γ -FeSiAl₃, occasionally forms in such alloys. One other phase, namely Fe₂SiAl₄, is referenced by Mondolfo as metastable in the Fe–Al–Si system, requiring very small amounts of manganese, chromium, or copper for its stabilisation. A summary of this information is given in Table 2.

In the original study of Takeda and Mutazaki,^[56] six ternary phases were identified using thermal analysis, metallography, and some X-ray work. These results are summarised in Table 3.

A critical evaluation of all published information on the Fe–Al–Si system by Rivlin and Raynor,^[29] compared the results of the early Japanese study with the crystallographic and compositional data of more limited recent studies. Rivlin and Raynor concluded that four of the six phases identified by Takeda and Mutazaki have been confirmed by the findings of the later studies, though considerable disagreement exists between different workers as to the exact stoichiometry and crystal structures of specific phases. The four confirmed phases suggested by Rivlin and Raynor are given in Table 4.

When comparing the data in Tables 3 and 4 with those in Table 2, the alternative ternary phase nomenclatures of Rivlin and Raynor (Tables 2 and 3) and Mondolfo (Table 2) should be noted. To avoid confusion, the present authors have cross-referenced the two sets of phase identity information by including the correspondence between the Mondolfo, and the Rivlin and Raynor phase identities.

The few published isothermal sections of the Fe–Al–Si system are nearly all confined to the aluminium corner of the ternary diagram. Dix and Heath,^[66] for example, proposed an empirical non-equilibrium isotherm at 560°C

Table 2 Fe–Al–Si phases^[30]

Nomenclature	Stoichiometry	Crystal structure	Composition, wt-%		
			Fe	Al	Si
α	Fe ₂ SiAl ₈	Hexagonal	30–33	55–65	6–12
β	FeSiAl ₅	Monoclinic	20–30	55–68	12–15

which summarised their metallographic findings for the coexistence of the phases now identifiable as $\theta\text{-FeAl}_3$, $\tau_5(\alpha)\text{-Fe}_6\text{Si}_5\text{Al}_{15}$, $\tau_6(\beta)\text{-FeSiAl}_4$, and silicon. The only other published isotherms relevant to Type 1 aluminising are those constructed by Denner and Kim^[68] using data from the work of Takeda and Mutazaki; these isotherms pertain to temperatures of 693 and 816°C. These workers emphasise that the sections are essentially schematic since they ignore inaccuracies suspected to exist in the original data regarding the phase boundaries of $\tau_5\text{-Fe}_6\text{Si}_5\text{Al}_{15}$ and $\theta\text{-FeAl}_3$, and take no account of the superlattices now known to exist in the $\alpha\text{Fe-Al}$ solid solution phase field.

Morphology and Phase Constitution of Hot Dipped Aluminised Steels

The literature contains many general descriptions of the structure of hot dip aluminised steels^[11,16–18,68–78] Most published information pertains to Type 2 hot dip aluminised

steels. This is somewhat surprising given the current commercial pre-eminence of the Type 1 material but probably results from the fact that the Type 2 material was commercially produced some years before the Type 1 grade.

Although the volume of hot dip aluminising literature is not great, research has been somewhat piecemeal in nature and lacks systematic development. This has meant, for example, that there are no fundamental studies comparing coating structures on pure iron with those on steels of different compositions. To hinder comparisons further, studies have often been performed over widely different dip times and temperatures and occasionally with melts containing an unspecified quantity of dissolved iron, or in the case of Type 1 aluminising melts, with different silicon contents in the range 2–11%.

The structure of hot dip aluminised steel coatings comprises a surface layer of Al–Si alloy (Type 1 hot dip aluminised steel), or ‘commercially pure’ aluminium (Type 2 hot dip aluminised steel). These outer coatings invariably contain isolated intermetallic inclusions within a matrix saturated with dissolved iron (in practice, saturation iron concentration at aluminising temperatures is about 2.5% for both coating types). Residing between the surface layer and the steel substrate is an alloy layer comprising distinct strata of Fe–Al–Si or Fe–Al intermetallic compounds.

It is a matter of empirical observation that not all the phases predicted by the respective Fe–Al–Si and Fe–Al phase equilibrium diagrams are observed in either the Type 1 or Type 2 coatings, with the exact identity of the phases present in each case remaining a matter of some controversy.

Transverse sections of typical Type 1 and Type 2 coatings are shown in Figs. 2 and 3, respectively. The presence of silicon in the Type 1 aluminising melt results in three important differences between Type 1 and Type 2 hot dipped aluminised steels:

- it greatly inhibits alloy layer growth so that the alloy layers of Type 1 aluminised steels are always appreciably thinner than those of the Type 2 material
- it changes the phase constitution of the alloy layer
- it results in the formation of a planar, steel/alloy layer interface characteristic of the Type 1 material; the corresponding serrated or ‘saw tooth’ interface being typical of the Type 2 material

Regarding the phase constitution of the Type 2 material, reference to information on the Fe–Al system (see Table 1 and Fig. 1) indicates that at typical aluminising temperatures a series of phase strata comprising Fe–Al solid solution phases, and three intermetallic phases of increasing aluminium content ($\zeta\text{-FeAl}_2$, $\eta\text{-Fe}_2\text{Al}_5$, and $\theta\text{-FeAl}_3$) should be present between the steel and outer solidified aluminium coating.

Fig. 2 Transverse section of Type 1 hot dipped aluminised steel; total coating thickness 24 µm

Fig. 3 Transverse section of Type 2 hot dipped aluminised steel; total coating thickness 42 µm

It appears that only one study claims to have identified all equilibrium phases in the coating structure,^[49] there otherwise being general agreement that in practice, only one phase can be easily and unequivocally observed (*see* Fig. 3).

Older work on the identity of this predominant intermetallic phase yields highly contradictory information, two studies reporting it to be θ -FeAl₃ overlying a zone of Fe–Al solid solution;^[79,80] one study claiming a two phase intermetallic layer of θ -FeAl₃ and ζ -FeAl₂, overlying an Fe–Al solid solution zone;^[81] and a fourth study claiming the sole presence of a θ -FeAl₃ layer.^[77]

These early investigations were initially further confused by a study by Gebhardt and Obrowski.^[82] These workers suggested that the major product phase was η -Fe₂Al₅, which they concluded was responsible for the prominent serrated steel/alloy layer interface. Further, these workers observed that between the serrated projections of this intermetallic resided a very thin second phase which they ascribed to α Fe–Al solid solution.

Subsequent investigations^[2,16,17,69,71,72,83–98] practically all agree with the basic tenet of Gebhardt and Obrowski's study that the predominant phase in Fe–Al (liquid) reaction diffusion is η -Fe₂Al₅, though there remained considerable disagreement over the presence and/or identity of minor phase constituents within the reaction zone.

The predominance of η -Fe₂Al₅ has subsequently been attributed to kinetic factors arising from the defect crystallography of this phase: the large number of aluminium vacancies along the *c*-axes of the orthorhombic cells are

thought to enable a greater diffusion rate of reactant species than in the θ -FeAl₃ or ζ -FeAl₂ phases.^[42,43,96] Hence, it is reasoned, η -Fe₂Al₅ grows at a much greater rate than the other intermetallic phases.

This defect crystallography is also thought by some workers to be responsible for the characteristic, serrated steel/alloy layer interface in Type 2 aluminised steels, since, it is argued, η -Fe₂Al₅ preferentially nucleates in the direction of the *c*-axes.^[69,96,99,100] Several studies also associate this morphology with ferritic substrates, austenitic substrates giving a linear interface.^[2,90,93,98,99,101] This last point is disputed by Kwon and Lee,^[102] who claim that not only austenitising elements such as nickel, but also ferrite stabilising elements such as chromium and silicon can result in a linear interface. These workers argue that the morphology arises from preferential nucleation of the phase on certain crystallographic planes of the substrate. Although it is now generally accepted that η -Fe₂Al₅ is the predominant phase in Type 2 aluminised steels, there is by no means universal agreement on the exact phase structure. Some workers, for example, claim the definite presence of a thin θ -FeAl₃ stratum between η -Fe₂Al₅ and the outer aluminium coating;^[11,69,71,83,103,104] Eggeler and co-workers^[69,71] having claimed to have verified its presence using transmission electron microscopy (TEM).

Such a layer, at dip times of less than 15 s, was suggested by Denner and Jones,^[73,87] these works also indicating the inclusion of θ -FeAl₃ particles within the dominant η -Fe₂Al₅ phase stratum. The absence of a coherent θ -FeAl₃

layer at longer dip times was attributed by these workers to both its dissolution into the melt and its rapid conversion to η -Fe₂Al₃. The implication of this assertion was that the presence of θ -FeAl₃ is only possible in melts saturated with dissolved Fe. These arguments were subsequently elaborated,^[105] it being pointed out that the presence of θ -FeAl₃ as a reaction product stratum *per se* is difficult to establish. This, they argued, arises because molten aluminium dissolves about 2.5%Fe at 700°C and cooling to the Fe–Al eutectic temperature (652°C) initiates separation of primary θ -FeAl₃. This may then grow on the surface of the η -Fe₂Al₃ phase stratum as well as within the matrix of the solidifying outer aluminium coating, as it cools.

Other authors^[106,107] have suggested that θ -FeAl₃ is likely to be absent from the coating structure because it decomposes at 558°C, forming η -Fe₂Al₃ and Fe₂Al₇. Such a reaction was first suggested to occur in aluminising, by Hughes and Moses,^[18] possibly on the grounds that Bradley and Taylor^[40] had claimed to observe this phase change during studies of the Fe–Al system. There is no evidence to substantiate these claims.

A further mechanism to account for the absence of an easily discernable θ -FeAl₃ phase has also been promulgated by Jones and Denner.^[105] This involves spalling of the phase into the melt, an underlying driving force for which is envisaged as being growth stresses generated within the layer. By analogy with many oxidation reactions, the implication is that beyond a certain limiting thickness, stresses within the layer forbid further compact formation, and continuous formation and spalling into the melt then occurs. Thus, without very careful metallographic examination, this layer would be so thin as to appear absent from the coating structure. The identity of intermetallic particulates within the outer coating matrix remains uncertain. Some workers claim θ -FeAl₃ inclusions,^[16,73,76,87,108] while others claim η -Fe₂Al₃.^[72,86]

The equivocal presence of a θ -FeAl₃ phase stratum is particularly surprising on thermodynamic grounds, since this appears the most favoured of all three Fe–Al intermetallic compounds relevant to aluminising: published data suggests that the Gibbs free energy change accompanying formation of this compound is considerably greater than for either η -Fe₂Al₃, or ζ -FeAl.^[2,109]

Although two studies have suggested the presence of ζ -FeAl₂ in Type 2 aluminised steels,^[49,81] no other studies support this finding. Ivanov^[109] suggests that this phase is metastable in hot dip aluminising and rapidly disproportionates to η -Fe₂Al₃ on formation. However, it is interesting to note that Bedford and Boustead^[110] detected this phase as a minor constituent in the alloy layer produced on annealing 'Elphal' (an experimental, diffusion bonded, aluminium coated steel, *see e.g.* Jackson.^[111] These workers found that intermetallic growth was initiated by the appearance, and subsequent limited growth of θ -FeAl₃. This was followed by formation and rapid growth of η -Fe₂Al₃ as thin needlelike precipitates between the original phase

and the steel substrate. Subsequently, small amounts of ζ -FeAl₂ were observed to form. Kwon and Lee^[112] have also reported the formation of ζ -FeAl₂ on annealing Fe/ η -Fe₂Al₃ diffusion couples at temperatures in the range 740–985°C and θ -FeAl₃ on annealing η -Fe₂Al₃/Al diffusion couples at temperatures greater than 660°C, while Nishida and Narita^[113] report ζ -FeAl₂ formation on annealing Fe/Al diffusion couples at 800°C. Although often cited in work on aluminising it is doubtful whether these investigations are of practical significance to the actual coating structures obtained in hot dipping.

Similar doubt can be cast on the relevance of Kokh's observations^[114] of ζ -FeAl₂ and Fe–Al solid solution zones in welded Fe/Al couples. Again, apart from early works which suggested the presence of Fe–Al solid solution zones^[71,80–82] the only recent studies to claim this are those of Karamysev *et al.*,^[49] Bahadur and Mohanty,^[83] and Coburn.^[11,76] Gebhardt and Obrowski's suggestion^[82] of a very thin α -FeAl solid solution phase between projections of η -Fe₂Al₃ at the steel interface in Type 2 material is an interesting observation in view of the results of several subsequent studies which have suggested the presence of a very thin zone of carbon enrichment ahead of the growing intermetallic phase front in both Type 2 and Type 1 materials. Such zones (again residing between the projections of the η -Fe₂Al₃ phase) were clearly visible in Denner's work.^[87] It now seems possible that Gebhardt and Obrowski mistook the formation of a thin carbon enriched zone for an α -FeAl solid solution zone. This is discussed below.

The phase constitution of the alloy layer present in Type 1 aluminised steels, like that of Type 2, is also the subject of earlier misleading research results.

Using aluminised steels dipped in a bath containing 1.1%Si, and detailed scanning electron microscope-electron microprobe analyses (SEM–EPMA), Lamb and Wheeler^[94] found an alloy layer with two distinct intermetallic strata. The inner stratum was reported as comprising η -Fe₂Al₃, this lying contiguous with the steel substrate, while the outer thinner layer comprised θ -FeAl₃; silicon was not detected in either phase but particles of θ -FeAl₃ were detected in the outer Al–Si coating matrix. Broadly similar conclusions were reported in an Al–2Si coated Type 1 aluminised steel by Nicholls.^[75]

Coburn,^[11] in an X-ray diffraction study of Type 1 specimens produced in baths containing 9–11%Si, concluded that the single detected intermetallic layer was composed entirely of silicon bearing η -Fe₂Al₃, this overlying a region of Fe–Al solid solution. In addition, he reported the presence of two distinct intermetallic phases in the outer coating matrix: one was described as light grey platelets of 'an Fe–Al compound', and the second as a dark grey, etchant resistant, acicular silicon rich component.

A similar single intermetallic stratum has been reported by Liu and Wu^[115] and Warnecke and Baumgartl^[116] in industrially produced Type 1 samples (as opposed to the laboratory prepared samples used in other studies). The

composition of this layer in the former study is reported as FeSiAl_2 and in the latter as $\text{Fe}_{1.5}\text{SiAl}_6$. These appear to correspond to $\tau_2(\gamma)\text{-FeSiAl}_3\text{-}\tau_5\text{-Fe}_3\text{Si}_2\text{Al}_{12}\text{-}\alpha\text{-Fe}_2\text{SiAl}_8$ (see Table 4). Unlike Coburn's study, no Fe–Al solid solution zone was found in either study.

In contrast, following metallographic and SEM–EPMA analyses of specimens dipped in melts containing 7–11%Si, Bühler *et al.*^[86] found alloy layers comprising two intermetallic strata. The composition of the outer stratum was reported as an $\alpha(\text{Fe–Al–Si})$ intermetallic compound overlying a much thinner stratum of $\eta\text{-Fe}_2\text{Al}_5$ or $\theta\text{-FeAl}_3$. The ternary Fe–Al–Si phase was indecisively assigned a formula of $\text{Fe}_3\text{SiAl}_{12}$ or $\text{Fe}_3\text{Si}_2\text{Al}_{12}$. Since crystal structures were not determined, again on the basis of the reported stoichiometry, this appears to correspond to the $\tau_5\text{-Fe}_3\text{Si}_2\text{Al}_{12}\text{-}\alpha\text{-Fe}_2\text{SiAl}_8$ (see Table 4). In this study, 'raftlike' inclusions of an intermetallic phase were observed in the surface Al–Si(Fe) coating matrix (reported as being iron saturated). These authors were also undecided about the exact identity of these particulates, assigning the formulae $\text{Fe}_2\text{Si}_2\text{Al}_9$ and $\text{Fe}_3\text{SiAl}_{12}$. The first formula suggests the phase is $\tau_6\text{-Fe}_2\text{Si}_2\text{Al}_9\text{-}\beta\text{-FeSiAl}_5$ while the second is suggestive of $\tau_5\text{-Fe}_3\text{Si}_2\text{Al}_{12}\text{-}\alpha\text{-Fe}_2\text{SiAl}_8$ (see Table 4). A recent investigation^[57] on the formation of intermetallic compounds during the solidification of Al–Fe–Si alloys containing 2%Fe and 2%Si, identified $\theta\text{-FeAl}_3$, $\alpha\text{-Fe}_2\text{SiAl}_8$, and $\beta\text{-FeSiAl}_5$ as equilibrium phase constituents. These phases are said to dominate on slow cooling, depending on the exact composition and cooling rate, but that a number of other intermediate non-equilibrium phases can also form, again, depending on specific composition and cooling rates.

Fotouhi^[117] suggests that the phase constitution of Type 1 aluminised steels depends on dipping temperature. This work involved dipping low carbon steel sheet in an aluminising bath containing 11%Si for times of up to 300 s at temperatures varying from 675 to 900°C. This was followed by X-ray diffraction and SEM–EPMA analyses, principally on alloy layers formed on immersions of 300 s. At temperatures below about 750°C, Fotouhi found that the alloy layer invariably comprised two distinct intermetallic strata. The outer, thicker stratum was unequivocally identified as $\alpha\text{-Fe}_2\text{SiAl}_8$ (i.e. $\tau_5\text{-Fe}_3\text{Si}_2\text{Al}_{12}$) while the inner, much thinner stratum corresponded to $\theta\text{-FeAl}_3$. At temperatures greater than ~750°C, the $\theta\text{-FeAl}_3$ stratum no longer formed, the alloy layer consisting entirely of $\alpha\text{-Fe}_2\text{SiAl}_8$. Possible variations at immersion times of less than 300 s were not addressed in this study because of analysis difficulties, Fotouhi reporting that even at relatively short dipping times and lower temperatures, 'extensive dissolution and spalling' of the outer intermetallic stratum was observed to occur. As Denner and Kim have subsequently pointed out,^[68] the major reason for confusion regarding the phase constitution of Type 1 aluminised steels has been the absence of appropriate isothermal sections of the Fe–Al–Si system.

In an attempt to clarify the structure of typical Type 1 hot dipped aluminised low carbon steels, these workers^[68] have performed optical metallography, X-ray diffraction, and SEM–EPMA analyses and correlated their findings with schematic isothermal sections constructed from original work by Takeda and Mutazaki.^[56] At dipping temperatures up to about 730°C, and dipping times of less than ~900 s, the alloy layer was found to consist of a thick, light etching stratum of a ternary Fe–Al–Si intermetallic compound, identified as $\tau_5\text{-Fe}_2\text{SiAl}_7$. Between this layer and the steel substrate, a thinner, darker etching stratum of $\eta\text{-Fe}_2\text{Al}_5$ was observed. This layer was found to contain isolated precipitates of $\theta\text{-FeAl}_3$. Both the $\eta\text{-Fe}_2\text{Al}_5$ layer, and the occluded precipitates of $\theta\text{-FeAl}_3$ within this layer, were found to contain unspecified quantities of silicon. The interface between the surface Al–Si coating, and the outer $\tau_5\text{-Fe}_2\text{SiAl}_7$ intermetallic stratum, was generally highly irregular, this being attributed by Denner and Kim to dissolution effects in the aluminising melt.

On immersion times greater than ~900 s, at temperatures up to 730°C, a distinct, but discontinuous layer of $\theta\text{-FeAl}_3$ was observed to grow between the $\tau_5\text{-Fe}_2\text{SiAl}_7$ layer and the inhomogeneous $\eta\text{-Fe}_2\text{Al}_5$ layer adjacent to the steel. At higher dipping temperatures on similar immersion times, the $\theta\text{-FeAl}_3$ phase appears as a continuous layer, separated from the $\eta\text{-Fe}_2\text{Al}_5$ by a two phase $\eta\text{-Fe}_2\text{Al}_5\text{-}\theta\text{-FeAl}_3$ layer. The $\eta\text{-Fe}_2\text{Al}_5$ layer was not in this case observed to contain isolated $\theta\text{-FeAl}_3$ precipitates. At these higher temperatures one further very thin layer was observed to develop between the $\eta\text{-Fe}_2\text{Al}_5$ stratum and the steel. This, it is suggested, corresponds to $\zeta\text{-FeAl}_2$.

The foregoing observations of Denner and Kim^[68] represent the most detailed description of Type 1 aluminised steel coating morphology to date, concurring with the results of recent unpublished studies.^[118,119] However, the observations are not in agreement with the results of Eggeler *et al.*,^[70] who suggested that the Type 1 coating morphology produced in a melt containing 2%Si comprises $\eta\text{-Fe}_2\text{Al}_5$ and $\theta\text{-FeAl}_3$ strata. Both layers contained silicon, the solubility limit for which in both phases they suggest is about 2%. Although no silicon was found in the earlier study of Lamb and Wheeler,^[94] these two studies are in general agreement on the coating structure produced in a 2%Si melt. Although such a low silicon concentration is not a typical Type 1 aluminising composition (silicon contents are generally of the order 6–11%), it is appropriate to suggest that Type 1 phase morphology is dependent on bath silicon content in a way which has not been thoroughly investigated.

Some reference has already been made in this section to the possible presence of a carbon enrichment zone at the steel/alloy layer interface in Type 2 aluminised steels. This has been reported both in Type 1^[117,119] and Type 2 aluminising reaction.^[2,16,27,79,99,120–122]

The low solubility of carbon in Fe–Al intermetallic compounds^[123,124] was confirmed, in relation to aluminising,

by Tagaya *et al.*^[122] and found to fall in the range 0.11–0.45% at typical aluminising temperature. These researchers suggested that carbon enriched zones only form when the carbon content of the steel exceeded the solubility limit of carbon in the alloy layer. Hence, they reasoned, such zones are unlikely to form in steels with carbon contents of less than about 0.45%. No solubility data for carbon in Fe–Al–Si intermetallics were reported in this study.

In contrast to Tagaya *et al.*, Ryabov² implies that carbon enriched zones are always present at the substrate/alloy layer interface in all aluminised steels. Citing the work of Meyer and Bühler^[124] and Maslennikov and Molitilov^[125] among others, Ryabov argues that since carbon is unable to diffuse through Fe–Al intermetallics it becomes concentrated in a zone of the substrate adjacent to the growing alloy layer. He further suggests that aluminium may be chemically combined with carbon, forming binary carbides Al_4C and Al_3C , or ternary carbides of the type Fe_3AlC_x . This last suggestion was also made in previous studies,^[16,120,122] but in all cases experimental verification is lacking. However, the greater uniformity of the substrate/alloy layer interface in Type 2 aluminised, high carbon steels has been observed in several works^[2,90,93,98,101] and attributed to formation of pearlite within the carbon enriched zone.

As a corollary to this discussion Kwon and Lee^[102] have confirmed the presence of a linear phase front in high carbon steels and an earlier observation by Brandes^[126] that decarburisation does not occur during aluminising. However, no evidence was presented in this work for formation of a carbon enrichment zone at the steel/alloy layer interface.

Identification and Properties of Intermetallic Phases in Hot Dipped Aluminised Steels

The preparation of transverse sections of hot dip aluminised steels for metallographic examination is a demanding task requiring considerable experience and skill. The difficulties arise because of the composite nature of the material: the soft Al–Si or aluminium surface coating (containing intermetallic inclusions) bonded to a steel substrate by very hard and brittle intermetallic phases results in differential abrasion. This problem is compounded by galvanic effects between the three layers. This occurs when grinding in aqueous media and on acid etching using organic solvents: large differences in the rates of dissolution of the various phases are observed.

Although there have been no detailed studies devoted solely to the metallography of hot dipped aluminised steels, analogous works on hot dipped galvanised steels are worthy of consultation.^[126–128] To discriminate phases in optical microscopy, Nishida and Narita^[113] recommend the use of 2 vol.-% HF aq. etchant which is claimed to produce an unmistakable series of colour tints in the various intermetallic phases. An alternative method^[119] involves using successively finer alumina polishing suspensions, followed by light etching with 0.5% nital. This achieves

excellent phase contrast in both optical and SEM examination. Accentuation of alloy layer thicknesses by taper sectioning^[129] has also been found an extremely useful technique, especially in SEM–EPMA analyses of hot dipped aluminised steels. Bühler *et al.*^[186] claim that optical discrimination of phases is best achieved using an interference film technique involving coating the section with zinc selenide and illuminating with orange light at a wavelength of 605 nm. The technique of interference film microscopy has recently been reviewed by Quested and Bennett.^[130]

A general discussion of optical and SEM–EPMA identification of Fe–Al intermetallics has been given by Kowatschewa *et al.*,^[131] while a novel method of extracting Fe–Al and Fe–Al–Si intermetallics formed as insoluble residues via the electrolytic dissolution of aluminium alloys has been described by Ryvola and Morris.^[132]

Precise measurement of alloy layer thickness in hot dip aluminised steels is best achieved by metallographic means and determination of total coating weight per square metre of material gravimetrically: standard methodologies are available.^[133,134] Other methods of total coating thickness measurement have been discussed in detail by Plog and Crosby^[135] and Kutzelnigg.^[136]

Preparation of individual Fe–Al and Fe–Al–Si intermetallic compounds is a procedure fraught with difficulties. No fully comprehensive description of proven preparative methods is available, though general outlines of methods given by Ryabov^[2] and Kwon and Lee^[112] report the synthesis of η - Fe_2Al_3 used to construct Fe/ η - Fe_2Al_3 and Al/ η - Fe_2Al_3 diffusion couples. A novel method of θ - $FeAl_3$ isolation claimed by Gierek and Bajka^[108] involves controlled addition of iron to an aluminium melt. Apart from this last method, it seems that general preparation of individual phases involves prolonged annealing of stoichiometric amounts of pure reactants in an inert atmosphere from which oxygen is scrupulously excluded. Interestingly, Gellings and co-workers^[137,138] have provided a detailed description of the preparation of Fe–Zn intermetallic compounds.

Laboratory hot dip aluminising of steels is usually performed using various steel cleaning, pickling, and fluxing procedures.^[26,77,139] A greatly simplified method which does not involve the use of fluxes has recently been published.^[140]

As might be expected, very little information is available on the chemistry of Fe–Al and Fe–Al–Si intermetallic compounds. Hitherto, the most fruitful source of data has generally been the Soviet literature. Much of the information has been conveniently collated by Ryabov.^[2] Values for the standard enthalpy and entropy changes of formation (ΔH^θ and ΔS^θ , respectively, at 298 K), and the Gibb's free energy change on formation at 700°C (ΔG_{973K}), for various Fe–Al phases are given in Table 5. These data have been obtained from Ryabov^[2] and Ivanov.^[109] Reference thermodynamic values for Fe–Al–Si ternary phases, analogous to those of Fe–Al binary phases in Table 5, appear to be unavailable in the literature.

Table 5 Standard enthalpy and entropy changes (at 298 K) and Gibb's free energy changes (at 973 K) accompanying formation of Fe–Al phases^[2,109]

Phase	ΔH° , J mol ⁻¹	ΔS° , K ⁻¹ mol ⁻¹	ΔG_{973K} , J mol ⁻¹
θ -FeAl ₃	-112 560	95.6	-22 869
η -Fe ₂ Al ₅	-194 040	166.7	-19 636
ζ -FeAl ₂	-81 900	73.3	-16 999
α -FeAl	-51 240	51.0	-11 090
Fe ₃ Al	-57 372	28.0	-4827

Density ρ and standard molar volume M_v data for the phases θ -FeAl₃, η -Fe₂Al₅, and $\alpha(\tau_5)$ -Fe₂SiAl₈ are given in Table 6. Measured density values have again been gleaned from Ryabov.^[2] Standard M_v data (i.e. the molar volume corresponding to exact adherence to a specified stoichiometric composition) were calculated by Richards^[119] and have also been reported by Nishida and Narita.^[113]

Again, from a number of original Soviet works, Ryabov^[2] quotes the microhardness values of the phases θ -FeAl₃, η -Fe₂Al₅, and ζ -FeAl₂ as falling in the range 960–1500 kg mm⁻², increasing iron content apparently decreasing the hardness value; values for Fe₃Al and α -FeAl are reported as 660 and 270 kg mm⁻², respectively. Values for the ternary phases $\alpha(\tau_5)$ -Fe₂SiAl₈ and $\delta(\tau_4)$ -FeSi₂Al₄ are 1079 and 1147 kg mm⁻², respectively. Ryabov also reports thermal expansivity and resistivity data for various Fe–Al phases.

KINETICS OF HOT DIP ALUMINISING

Theoretical Background

In hot dip aluminising, alloy layer formation occurs by reaction diffusion. This can be defined as a reaction governed principally by the interdiffusion of reactants within a solid product phase or phases. Many excellent texts are available describing the theory of diffusion. However, there are surprisingly few theoretical descriptions of solid–solid and solid–liquid reaction diffusion phenomena, particularly where the formation of intermetallic compounds is involved.

From a consideration of the basic principles governing diffusion controlled reactions in the solid state,^[141–147] two important deductions can be made regarding reaction diffusion in aluminised steels:

Table 6 Density ρ and molar volume M_v values of important phases in hot dip aluminised steels

Phase	ρ , g cm ⁻³	M_v , mol cm ⁻³
θ -FeAl ₃	3.90	35.11
η -Fe ₂ Al ₅	4.11	59.99
α -Fe ₂ SiAl ₈	3.62	98.23

1. Provided chemical contact is maintained between homogeneous compact product phase strata, then at equilibrium, the growth of each phase of the alloy layer is volume diffusion (i.e. lattice diffusion) controlled. Thus, the kinetics of reaction can be represented by a parabolic rate equation of the form

$$y^2 = kt \quad k \text{ rate constant, } \mu\text{m}^2 \text{ s}^{-1} \quad (1)$$

or

$$y = k't^{0.5} \quad k' \text{ rate constant, } \mu\text{m s}^{0.5} \quad (2)$$

where y is the thickness (μm) of the alloy layer after a dip time of t (s).

2. Provided volume diffusion control is maintained throughout the course of the reaction (i.e. provided there is no fundamental change in the mechanism by which reaction occurs), the rate of reaction shows a linear, Arrhenius type temperature dependence

$$k = A \exp(E_A/RT)$$

where k is the reaction rate constant, A the frequency factor, E_A the reaction activation energy (J mol⁻¹), R the gas constant (J K⁻¹ mol⁻¹), and T the temperature (K) in question.

Theoretical justification for an overall parabolic growth law representing formation of one or more intermetallic phase layers has been provided by a number of works.^[142,148–153] In practice, deviations from parabolic kinetics are common.

In very general terms, positive deviations involving growth rates greater than predicted by parabolic laws are likely at short dip times. Here, the time exponent in Eq. 2 is >0.5 and linear or near linear kinetics are observed. This is usually associated with porous-cracked or incomplete alloy layers where diffusion paths short circuiting a volume diffusion mechanism are available. At longer dip times, negative deviations are usually observed. Here, the time exponent in Eq. 2 is <0.5 , with apparently very slow rates of growth occurring. This is most frequently attributed to dissolution and/or spalling into the melt of a proportion of the product alloy layer.

The physical significance of the activation energy E_A and frequency factor A values in the Arrhenius equation for reaction diffusion are somewhat obscure, i.e. such values cannot be assigned to a single specific process within the overall mechanism of reaction as, for example, is the case with gas phase reaction. However, calculated E_A values in aluminising can be intuitively interpreted as the activation energy for diffusion of the primary diffusing (i.e. rate determining) reactant species within the product layer. Several practical methods are available for determining the kinetics and energetics of aluminising reaction. These involve metallographic measurement of the thickness of

alloy layer produced, or determination of the amount of iron consumed in reaction. This last method can be performed by either direct metallographic measurement of the reduction in thickness of steel or its gravimetric determination after stripping the entire coating. Care must be taken to ensure the mathematical rationality of kinetic and temperature dependence determinations, especially in the selection of reaction rate constants for use in determining E_A values.

A true reaction rate constant k has dimensions of time^{-1} . Such constants can be obtained by plotting observed variations in alloy thickness with dip time (at constant temperature), deducing the appropriate rate equation, and thence determining the time required for a given thickness of alloy layer to be produced. In effect, the k values obtained by this method express the time required for formation of unit thicknesses of product and have dimensions of time^{-1} .

Alternatively, rate data can be plotted as the square of the thickness of the alloy layer (y^2) with dip time (t), the best fit to the parabolic Eq. 1 obtained, and the rate constant evaluated. Constants evaluated by this means have units of $\mu\text{m}^2\text{s}^{-1}$; E_A values obtained by plotting these rate constants bear comparison with published E_A values for self-diffusion of iron and aluminium, and, also with the limited E_A data available for tracer diffusion of iron and aluminium in specific Fe–Al intermetallic phases.^[142,154,155] Such comparisons facilitate some insight into the likely mechanism of reaction.

Aluminising Kinetics

Although Stroup and Purdy^[78] and Hanink and Boegehold^[27] reported aspects of work on aluminising kinetics it appears that the earliest detailed paper is that of Gebhardt and Obrowski.^[82] These workers investigated the interaction between pure iron and pure aluminium for immersion times of 10–60 min at 800°C. Using a dilatometric technique to determine alloy layer thicknesses, they were unable to deduce parabolic growth laws. This study was followed by that of Kapoor *et al.*^[156] This involved a pure aluminium melt and immersion times of up to 120 s at 700, 750, and 800°C. The precise compositions of the plain carbon steels used were not reported but large negative deviations from parabolic growth were observed: power growth laws were deduced having time exponents in the range 0.27–0.38.

The first fully detailed investigation of aluminising kinetics was that of Heumann and Dittrich.^[96] These workers argued that the inability of Gebhardt and Obrowski to establish parabolic kinetics arose from their reliance on the measurement of mean alloy layer thickness values. Dipping pure iron in iron saturated aluminium melts, for times up to 960 s at 715, 846, and 944°C, these workers were able to establish near parabolic kinetics provided maximum alloy layer thickness values were used in the calculations.

These data yielded an E_A value of 55 kJ mol⁻¹, which was attributed to the activation energy of the interdiffusion coefficient in $\eta\text{-Fe}_2\text{Al}_5$, the main reaction product. The relatively low temperature dependence was explained in terms of the odd defect crystallography of $\eta\text{-Fe}_2\text{Al}_5$ ^[42,43]: the high aluminium vacancy concentration along the c -axes of the orthorhombic cells of $\eta\text{-Fe}_2\text{Al}_5$ permitted high diffusional mobility of reactant aluminium atoms.

Subsequently, Coburn^[11] reported the results of a study designed to emulate industrial practice. Continuous aluminising of a low carbon industrial steel substrate was simulated on a laboratory test rig. Short immersions of less than 16 s in pure aluminium were performed at temperatures in the range 680–740°C. Re-examination of Coburn's data at temperatures below 727°C gives near parabolic growth laws and a reaction E_A value >200 kJ mol⁻¹. A further investigation by Owadano and Yusa^[103] used low carbon steel rod as substrate material, in pure aluminium, at temperatures in the range 700–1000°C. Here immersion times of up to 120 s were employed. The results gave linear growth laws with a reaction E_A value of 80 kJ mol⁻¹.

These early studies have been critically appraised by Denner and Jones,^[73,105] who claim that the disregard of alloy layer dissolution and spalling effects during immersion makes an adherence to parabolic kinetics difficult to establish. In their study,^[73] the effect of alloy layer dissolution on observed kinetics in a pure aluminium melt at 704°C was accounted for by calculating the thickness equivalent of dissolved alloy layer using the Nernst–Brunner equation.^[157] Dissolution rate data were obtained from a study by Eremenko *et al.*^[158] For dipping times of up to 300 s, a linear relationship between the thickness of dissolved alloy layer and the immersion time was computed. By adding these values to the mean alloy layer thickness values, parabolic growth laws in a variety of substrates for dip times up to 120 s were determined. Negative deviations from parabolicity at times greater than 120 s (particularly evident at higher temperatures) were attributed to stresses generated within the alloy layer which eventually cause spalling of the layer on attaining a certain limiting thickness. Calculated E_A values for the reactions fell in the range 170–195 kJ mol⁻¹ depending on substrate carbon content. Slightly higher rates of reactivity were found for pure iron than for low carbon steel.

Similar negative deviations from parabolicity at long dip times were also reported by Langenscheid and Klein^[85] for low carbon steels in aluminium melts with iron concentrations below saturation level. In this study, the maximum alloy layer thickness value produced on dipping at 700°C was used to establish the kinetics, but no attempt was made to account for dissolution effects.

In a subsequent study by Yermenko *et al.*,^[159] an equation was derived from theory which enabled the prediction of the thickness of the alloy layer produced on dipping pure iron in pure aluminium at 700°C. In essence, this equation is a combination of the Nernst–Brunner exponential

law for dissolution of solids in liquids and the parabolic law for alloy layer growth kinetics. Reasonable agreement between theory and experiment was obtained. This was particularly evident at longer dip times, contrary to the findings of Denner and Jones.^[73] In support of an original suggestion by Heumann and Dittrich,^[96] Yeremenko and colleagues assert that dissolution and spalling do not occur in iron saturated melts since essentially parabolic laws were obtained by Heumann and Dittrich in such melts.

This assertion seems to ignore Heumann and Dittrich's use of maximum alloy layer thickness data in their calculations of kinetics. This probably reduces the magnitude of dissolution and/or spalling effects and thus compromises both groups of workers deductions. Notwithstanding this, Yeremenko and co-workers are supported in their conclusions by the results of a recent study by Eggeler *et al.*,^[69] who investigated the reactivity of low carbon steel at 688°C. These workers also argue that deviations from parabolic growth are only observed in pure aluminium melts or melts not saturated with dissolved iron. Such deviations occur, they suggest, as a result of an exponentially time dependent 'Iron enrichment' of the unsaturated melt. Enrichment is said to occur via dissolution and spalling, its exponential time dependence being the reason, they claim, why Denner and Jones found negative deviations from parabolicity at long dip times: their linear relationship between dissolution and dip time becomes an underestimate of the alloy layer lost at long dip times.

As a consequence of their findings, Eggeler and co-workers attribute the discrepancy in E_A values between Denner and Jones and Heumann and Dittrich to differences in the iron concentrations of their melts. As an additional factor for the discrepancy, they point to their own results indicating a temperature dependence between the mean and maximum alloy layer thickness ratio. For an initially pure aluminium melt, they report E_A values calculated from mean and maximum alloy thickness data of 104 and 87 kJ mol⁻¹ respectively, while analogous data from an iron saturated melt yield values of 155 and 34 kJ mol⁻¹.

The deleterious effects of a thick brittle alloy layer on the mechanical properties of hot dip aluminised steels is well documented.^[11,76,160-164] To reduce alloy layer growth and improve formability, silicon additions of up to about 11% are used in Type 1 aluminising baths.

The literature contains many general descriptions of the effect of silicon in hot dip aluminising,^[11,16,27,68,70,75,77,78,82] the original observation having been made by Röhrig^[165] and a patent on the industrial application granted to Oganowski *et al.*^[166] The decrease in alloy layer thickness produced by additions of silicon to an aluminising bath are shown in Fig. 4. As can be seen, the data of both Stroup and Purdy^[78] and Coburn^[11] suggest an initially high retarding effect which gradually declines as further silicon is added. Considering form-ability and coating brightness properties in addition to reductions in alloy layer thickness, Coburn^[11] suggests an optimum silicon addition of 8.5–9.5%.

Fig. 4 Effect of melt silicon concentration on alloy layer growth in hot dip aluminising

The specific effect of a 10%Si addition on observed kinetics at 693°C is shown in Fig. 5.^[68] As is evident from both Figs. 4 and 5, this silicon addition results in an ~80% reduction in alloy layer thickness: further addition of silicon does not result in any greater decrease in alloy layer thickness.

The mechanism by which silicon reduces alloy layer thickness in aluminising remains controversial. The essence of the controversy relates to the role of silicon in dissolution and/or alloy layer spalling during dipping. As a result of their study of Type 2 which indicated that aluminium was the chief diffusing species, Heumann and Dittrich^[96] argued that silicon acts by occupying the large number of aluminium vacancies on the *c*-axes of the orthorhombic cells of η -Fe₂Al₅. This blocks rapid aluminium diffusion paths in this phase, aluminium being the only migratory species in their view. This explanation has been supported by Ryabov,^[2] Nicholls,^[75] and Ito *et al.*^[167] In contrast, Lainer and Kurakin^[168] concluded that the effect of silicon arises from the formation of Fe–Al–Si ternary phases which nucleate and grow more slowly than η -Fe₂Al₅. Further, these authors strongly dispute Heumann and Dittrich's view that aluminium is the primary diffusing species in Type 2 aluminising, claiming, on the basis of solid state diffusion experiments, that iron is the faster diffusing species.^[169] Subsequently, Kurakin^[170] expressed the view that the primary diffusing species in Type 2 aluminising was

Fig. 5 Effect of melt silicon: comparison of Type 1 and Type 2 growth kinetics at 693°C^[68]

iron, while in Type 1 aluminising it was aluminium. This apparent paradox was explained in terms of a disruption of steel/ η -Fe₂Al₃ interfacial contact in Type 2 aluminising which is not apparent in Type 1 aluminising where silicon retards the growth of this phase. The disruption was attributed by Kurakin to volume changes accompanying reaction. However, similar observations of interfacial disruption by Heumann and Dittrich were cited as evidence to substantiate their claim: disruption was caused by void coalescence occasioned by excessively rapid inward migration of aluminium.

Generally, a solid state diffusion inhibiting effect by silicon is supported by evidence of reductions in coating substrate alloying rates on annealing Type 1 hot dip aluminised steels^[96,119,171,172] and aluminium coated, high silicon containing steels.^[110] In addition there is evidence of substrate silicon reducing alloy layer growth rates during hot dipping.^[2,90,93,102,173] In spite of this, many workers^[16,105,117,120,174] contend that the major effect of silicon in Type 1 aluminising is its ability to increase the dissolution rate of the alloy layer. Thus, it is claimed, a thinner layer is produced in the resulting material. Much effort has been expended on quantifying the effects of dissolution on observed aluminising kinetics,^[2,73,105,120,158,159,175-180] though the results remain contentious.

A stark demonstration of the confusion regarding the effect of silicon has been provided by Schlösser and Knauschner.^[181] On continuous aluminising of a

low carbon steel in an 11%Si melt at 610–700°C, for a dip time of 4 s, these workers were unable to detect any increase in alloy layer thickness with increases in bath temperature. This was attributed to the effect of silicon, no mechanistic explanation being offered. A more detailed study on the effect of silicon by Eggeler *et al.*^[170] fails to confirm expedition of alloy layer dissolution by silicon, and thus corroborates the explanation that silicon effects a retardation of diffusion in the solid state. Eggeler and co-workers were unable to detect any significant differences between the rates of iron enrichment (it is presumed that this term was used to cover both dissolution and spalling) of initially iron free, pure aluminium, and Al–2Si melts at temperatures in the range 780–792°C at dip times up to 900 s. In conclusion, these workers strongly reaffirmed their earlier agreement^[69] with the Yermenko *et al.* study^[159] that iron enrichment of iron saturated aluminising melts does not occur.

On the basis of the most recent research^[118,119] this conclusion seems untenable. In these studies work was performed with iron saturated, 11%Si containing melts, at temperatures in the range 670–730°C. A variety of steel grades used in industrial aluminising, in addition to experimental nickel and chromium containing substrates, were the subject of the investigations. All the substrates showed broadly similar kinetic trends. At short dip times of less than about 60 s, alloy layer growth could usually be approximated to parabolic growth laws except at very short dip times of less than about 10 s, when positive deviations from parabolicity (i.e. tendencies to linear kinetics) were sometimes evident. Conversely, at longer dip times in the range 60–1200 s, pronounced negative deviations from parabolicity were always present. In some of the steels examined, these deviations were so great that the alloy layer produced after dipping for 1200 s was actually thinner than the alloy layer obtained after dipping for 600 s.

It is noteworthy that these general trends were apparent regardless of whether mean or maximum alloy layer thickness data were used, though Clements^[118] did establish that better approximations to parabolicity were obtained when reductions in substrate gauge (namely, the amount of steel lost during dipping) were used to determine kinetics. The variations in observed kinetics complicated calculations of E_A values, though generally, all aluminising reactions showed fairly high temperature dependences of greater than $\sim 130 \text{ kJ mol}^{-1}$. Using a combination of SEM–EDAX and X-ray diffraction analyses, both authors^[118,119] were in agreement that the outer phase stratum of the alloy layer on plain carbon steels comprised α -Fe₂SiAl₈ overlying a thinner η -Fe₂Al₃ phase layer.

Further, both studies produced metallographic evidence strongly indicating that alloy layer spalling occurs at all immersion times but particularly at times greater than about 120 s. Richard's work^[119] suggested that detachment of the alloy layer occurs principally at the α -Fe₂SiAl₈/ η -Fe₂Al₃

phase interface. SEM–EDAX analyses of detached–isolated intermetallic inclusions in the outer coating matrix assuredly demonstrated that these inclusions were of the same composition as the outer phase of the adjacent alloy layer. Reference to the photomicrograph in Fig. 6 clearly shows the detachment process.

In the view of Richards, previous studies failed to distinguish adequately between dissolution and spalling of the alloy layer. The first process was envisaged as ceasing on iron saturation of the melt, while the second process continues during the whole immersion–reaction period. It was reasoned that only on longer immersions, as alloy layer growth diminishes roughly in accord with parabolic kinetics, does spalling of the alloy layer become significant to the measured alloy layer thickness. Richards further suggested that since silicon was also observed to reduce the rate of solid state diffusion in aluminised steels,^[119] it decreases the observed rate of reaction in Type 1 hot dipping by both reducing the rate of solid state diffusion and enhancing the rate of alloy layer spalling. This was accounted for by suggesting that the presence of silicon in the crystallographic defects of the inner η -Fe₂Al₃ phase stratum of Type 1 aluminised steels caused a diffusion discontinuity between this phase and the outer α -Fe₂SiAl₈ phase. This leads to void formation at the phase interface and a consequent tendency to detachment of the outer phase into the melt. In addition to the foregoing arguments, it was also argued that previous workers^{3[69,70,159]} suggestion that iron enrichment of iron saturated melts does not occur is a conclusion directly contrary to industrial aluminising experience. Here, it is universally acknowledged that iron saturation of the bath does not prevent the continuous accrual of substantial amounts of intermetallic dross in the melt. This dross has to be periodically removed to avoid inclusion in the outer coating and serious impairment of its appearance.^[4]

In addition to the quantitative studies of kinetics, there have also been phenomenological studies of the effect of bath and steel alloying additions in hot dip aluminising. Excluding the use of zinc in Zn–Al alloy coated strip products, the only commercially important alloying addition to aluminising baths proper is silicon. However, the influence

of other bath additions have been studied, the principal aim being to effect alloy layer thickness reductions more effectively than with silicon.

Early studies have been reviewed by Denner and co-workers.^[14] Easily the most comprehensive work on bath additions is still that of Gittings *et al.*^[77] These workers used aluminium melts alloyed in a range of proportions with each of 19 different elements (including copper, manganese, magnesium, antimony, tin, nickel, chromium, cobalt, calcium, and beryllium), the selection being restricted to those having some solid solubility in zinc. Specimens were dipped for 20 s at 675°C, with changes in alloy layer thickness being expressed in terms of a percentage change on the value obtained with pure aluminium. Only tin was found to increase alloy layer growth, all other elements effecting marginal reductions in thickness. The only exceptions were beryllium, silicon, and copper which were found to decrease alloy layer thickness by more than 50% in each case.

In the case of beryllium, additions of 0.3–2.0% were found to reduce alloy layer thicknesses by about 70%. Such reductions are commensurate with additions produced by about 8%Si. Compared with silicon, better formability and appearance properties also resulted. The results for beryllium have been corroborated by Coburn,^[11] who also found that copper additions have no effect. Such additions would in any case compromise the corrosion resistance of the coating.^[14] In spite of the effect of beryllium its use in commercial hot dip aluminising is totally precluded on toxicity grounds. The effect of beryllium has also been reported in the Soviet literature,^[12] as have the effects of nickel, manganese, magnesium, and copper in Type 2 melts. The results for magnesium and copper generally accord with those of Gittings and co-workers. However, 0.5%Ni additions, and additions of 1–3%Mn were found to cause alloy layer thickness increases of about 50% at 720–730°C.

The effect of titanium additions has also been investigated by Gebhardt and Obrowski^[82] and Kapoor and co-workers,^[156] and both claim it has little effect in concentrations up to 2%. Janecky^[182] claims an 85% decrease in thickness with a 0.1%Ti addition, while Heumann and Dittich^[96] report that titanium and silicon, when present in concentrations of 2 and 0.04%, respectively, act

Fig. 6 Transverse section of Type 1 hot dipped aluminised steel; total coating thickness 24 μ m: note detachment of alloy layer into melt

synergistically, producing reductions in alloy layer thickness commensurate with a sole 6%Si addition. It is interesting to note that the unavoidable presence of dissolved iron in the outer coatings of aluminised steels has been claimed to reduce its formability and reduce its corrosion resistance.^[183]

In spite of its fundamental importance, the effect of steel composition on aluminising kinetics has not been systematically and comprehensively investigated. Several studies^[11,73,87,120,121,174,184,185] have established that with increasing carbon content of the steel, the rate of alloy layer growth decreases in Type 2 melts. Ryabov and co-workers^[2,90,173] found after immersions of 120 s at 750°C a minimum reactivity in the range 0.2–0.56% carbon occurred at about 0.3%C, this composition having an alloy layer thickness some 25–30 µm less than the range average of about 130 µm.

The decrease in reactivity with increasing carbon content is paradoxical, since several studies have also suggested that increasing carbon content decreases the rate of dissolution of the alloy layer.^[120,174,179] No satisfactory explanation can be offered for the effect of carbon though Ryabov,^[2] Denner,^[87] and Gürtler and Sagel^[98] associate the retardation of reaction to the formation of pearlite in the carbon enriched zone at the steel/alloy layer interface.

Langenscheid and Klein^[85] have reported that increasing the interstitial nitrogen content of low carbon steel markedly reduces alloy layer growth in Type 2 melts. On dipping a rimmed steel, effectively devoid of nitrogen stabilising elements such as aluminium and titanium, for 5 s at 700°C, these workers established that the alloy layer thickness was reduced from an average of about 35 µm to about 10 µm when the free nitrogen content of the steel increased from 0.002 to 0.055%. No explanation for the effect of interstitial nitrogen was offered, though a similar effect appears operative on annealing hot dip aluminised steels (see the section “Elevated temperature reaction diffusion in hot dipped aluminised steels” below).

The effectiveness of small additions of tungsten and molybdenum in reducing alloy layer formation in pure aluminium was first noted by Hauser^[186] and subsequently confirmed by Coburn,^[11] Hanink and Boegehold,^[27] Whitfield and Sheshunoff,^[187] and in the case of molybdenum by Moriyama *et al.*^[93] and Ryabov and co-workers.^[2,90,99,173] Quantification of the effect of tungsten is lacking though Coburn suggests the reduction in reaction rate is similar to that produced by carbon. Ryabov's work in the field suggests that an optimum addition of 1% molybdenum reduces alloy layer thickness by about 80%.

The study by Moriyama and his colleagues also established that small additions of bismuth, nickel, copper, and silicon, either singly or jointly, all resulted in significant reductions in alloy layer thickness. Referring to the Ryabov studies cited above, the elements nickel, manganese, silicon, molybdenum, titanium, chromium, vanadium, and zirconium, when alloyed with Armco iron, were all found

capable of retarding alloy layer growth in Type 2 melts after 180 s immersion at 750°C. Since individual additions of these elements varied from substrate to substrate, comparisons of relative reactivity reduction are difficult. However, it appears that manganese and molybdenum were found more effective than carbon and silicon, while nickel was more effective than chromium. An optimum 8% nickel addition resulted in a 90% reduction in alloy layer thickness while chromium additions in the range 2–20% produced a reduction of about 60%. The magnitude of the reductions produced by silicon, titanium, vanadium, and zirconium were not reported. On the basis of all the results, Ryabov's general conclusion was that ferrite stabilising elements are less effective inhibitors of alloy layer growth in Type 2 aluminising than austenite stabilising elements. In broad terms, this was attributed to the very low solubility of aluminium in γ -Fe and the relatively lower rate of iron self-diffusion in γ -Fe.

Commercial interest in the effect of substrate additions has been largely confined to chromium; the limited published information on which has dealt almost exclusively with the improvements in the corrosion and oxidation resistance of the steel base. Details of aluminising kinetics have not been reported, but major changes in aluminising practice are said to be required since chromium bearing substrates are claimed difficult to wet by conventional technology, especially with silicon containing melts.^[188] This is undoubtedly because conventional reducing furnaces operate at an insufficiently low oxidising potential to prevent oxidation of chromium. The resulting chromia film acts as a barrier to reaction between the molten aluminium coating alloy and the steel substrate. This difficulty appears to have generated much research with a number of patents being granted for aluminising chromium bearing strip.^[189–199]

The effect of substrate composition on Type 1 aluminising kinetics has recently been investigated in detail by Clements^[118] and Richards.^[119] Richards has confirmed the aluminising rate retarding effect of substrate nickel, examined the kinetics of aluminising Type 409 stainless steel and established that higher rates of aluminising reactivity are present in titanium stabilised, interstitial free substrates. This last result concurs with industrial aluminising experience where such steels are known to produce relatively thicker alloy layers for a given dip time–temperature regime than their conventional aluminium killed and rimmed steel equivalents. Clements has investigated in detail the aluminising kinetics of a range of novel composition steels containing 2–9%Cr. This work suggests that chromium markedly expedites the rate of aluminising at 670°C but decreases the rate at 730°C. Copious spalling of the alloy layer was observed at all temperatures, particularly at times in excess of about 60 s. This was especially pronounced at the higher temperature and interpreted as the cause of the apparent decrease in reactivity. These deductions elaborate published information on the effect

of chromium substrate additions^[90,102] and may well prove of some industrial interest. In particular, contrary to the limited published information, neither Richards nor Clements found that chromium bearing substrates presented special difficulties in laboratory hot dip aluminizing. Both workers found that such substrates were easily wetted by the Type 1 melt employed.

ELEVATED TEMPERATURE REACTION DIFFUSION IN HOT DIPPED ALUMINISED STEELS

When hot dipped aluminised coated steels are heated, a temperature is reached at which a significant rate of coating–substrate interdiffusion is initiated. As a result, the alloy layer increases in thickness and eventually ‘grows through’ to the surface of the material. When this occurs, the outer aluminium or Al–Si coating will have been completely consumed in reaction diffusion, the fully alloyed coating of intermetallic compounds appearing matt grey. Generally, the Type 1 grade is used in preference to the Type 2 grade for elevated temperature applications largely on the grounds that its thinner alloy layer renders it less susceptible to cracking on forming operations and hence less prone to oxidation when heated.^[11,68]

There is considerable disagreement on the temperature at which significant coating–substrate alloying is initiated in hot dipped aluminised steels. For Type 1 aluminised low carbon steels, the reported temperature is in the range 360–580°C.^[10,13,16,68,172,200–205] Type 2 aluminised steels are reported as showing significant alloying at temperatures in the range 380–600°C.^[2,17,18,78,96,168–170,172,206–208] though there are reports of significant rates of alloying in Fe–Al diffusion couples at temperatures as low as 200°C.^[209]

In both Type 1 and Type 2 aluminised steels, preliminary deformation of the substrates and deformation of the as produced materials often markedly reduces the temperature at which rapid, solid state reaction diffusion occurs.^[11,16,76,172,206,210] Low temperature coating–alloying at severely deformed areas has proved particularly problematic in Type 1 hot dip aluminised steels used in gas heating appliances.^[211] According to Denner and Kim,^[68] the phase constitution of the fully alloyed coating of Type 1 hot dip aluminised steel depends on the temperature and period of exposure. At various times in service the coating comprises strata of τ_5 -Fe₂SiAl₇, silicon containing θ -FeAl₃, η -Fe₂Al₅, ζ -FeAl₂, and α -Fe–Al solid solution. They further assert that though increased temperatures expedite the conversion of intermetallic phases to α -Fe–Al solid solution, oxidation protection will continue to be afforded by this phase provided the aluminium concentration does not fall below a certain limiting value. This value depends on temperature, and represents the minimum aluminium

concentration required to form a protective alumina (Al₂O₃) film at the particular temperature.

For the Type 2 material the fully alloyed coating is reported to comprise mostly η -Fe₂Al₅.^[2,96,169] After further heating, ζ -FeAl₂ and α -Fe–Al solid solution are also reported present; eventually the coating entirely comprises α -Fe–Al solid solution.^[212]

Generally, Type 1 hot dip aluminised steels are not recommended for service temperatures in excess of 650–690°C because of a tendency to coating delamination.^[9,10,68,72,76,167,205,213,214] At least one authority deems this temperature too high: for use in domestic heating appliances recommendations stipulate that Type 1 hot dip aluminised steel is not suitable for continuous use at temperatures above 500°C.^[215] This standard is imposed because of the occasional delamination of fully alloyed coatings on thermal cycling. The mechanism which gives rise to delamination at elevated temperature remains obscure. Denner and Kim^[68] argue that the fissures which preceded coating spalling emanate from within the η -Fe₂Al₅ phase at a location close to the original steel/alloy layer interface in the as produced material. These workers suggest that the cracks occur as a result of void formation and coalescence, volume changes accompanying phase change, and thermal expansivity mismatch on thermal cycling.

Elevated temperature spalling due to void formation, principally in the η -Fe₂Al₅ phase, is an attractive explanation given the known high diffusional mobility of aluminium atoms in this phase and the propensity for interfacial decohesion during solid state annealing.^[96,169,170] It is interesting to note that decohesion is apparently not observed in clamped Al/ η -Fe₂Al₅ diffusion couples.^[112] Void formation and the volume changes occurring during phase transformation are also known to be greatly exacerbated by the complex combination of residual tensile and compressive forces resulting from cold working and subsequent heating of the coating.^[160–163,216] Spalling mechanisms in brittle coatings have been discussed in detail by Evans *et al.*^[217]

Again, despite its obvious importance, studies of Fe–Al and Fe–Al–Si solid state reaction diffusion kinetics are surprisingly very sparse. In a limited study by Shibata *et al.*^[104] the interaction between pure aluminium and pure iron was investigated at several temperatures in the range 605–655°C for annealing times of 12–96 h. They were unable to establish unequivocally parabolic growth kinetics for the unidentified product layer at all the temperatures investigated and report a linear growth law at 655°C. The estimated E_A value in the temperature range 605–655°C was 222 kJ mol⁻¹. Similar studies by Ryabov^[2] involving the annealing of aluminium coated iron at temperatures in the range 540–650°C give approximate parabolic kinetics at temperatures of 540, 570, and 600°C. However, at 650°C, parabolic growth in the first 30 min was followed by rapid linear growth of the alloy layer. Ryabov calculated a reaction E_A value of 105 kJ mol⁻¹ for initial parabolic growth in the temperature range 540–650°C.

A comparison of the results of the Ryabov and Shibata studies shows very large discrepancies in reaction diffusion rate. In the Ryabov study, 6 h annealing at 650°C results in an alloy some 473 μm thick, of which $\sim 80 \mu\text{m}$ comprised $\theta\text{-FeAl}_3$, while the remainder was $\eta\text{-Fe}_2\text{Al}_5$. A similar period of annealing at 655°C in the Shibata study produces a total product layer less than 10 μm thick. Following his investigations, Ryabov explained the previous conflicting conclusions of Heumann and Dittrich,^[96] and Lainer and Kuraknn^[168–170] on the identity of the primary diffusing species in Fe–Al reaction diffusion, in terms of aluminium being the faster diffusing species in Fe–Al (liquid) interactions while iron is the faster species in Fe–Al (solid) interactions.

In their results, Makunin *et al.*^[218] noted similar large variations in the rates of solid state Fe–Al reaction diffusion to those apparent in the Ryabov and Shibata studies. This they concluded resulted from the presence of oxide(s) at the reaction interface. A more detailed follow up study by Zheladnov *et al.*^[206] confirmed this conclusion, strongly suggesting that observed rates of reaction diffusion were dependent on substrate trace oxygen content. These workers used a hot stage microscopy technique to measure the time required for the growth of $\eta\text{-Fe}_2\text{Al}_5$ nodules of 1 μm diameter in specially prepared Fe–Al couples, the iron component of which contained controlled trace amounts of oxygen. The experiments demonstrated that at temperatures between 300 and 600°C, there was no clear temperature threshold at which reaction diffusion was initiated in low oxygen containing iron substrates. Higher oxygen containing substrates showed no reaction in this range, but reacted rapidly at temperatures greater than about 600°C. X-ray analyses suggested that this initiation temperature coincided with the change from amorphous alumina to γ -alumina, this being present as a thin film in the region of the reaction interface

This change was believed to facilitate interdiffusion of Fe–Al reactants which had hitherto been hindered by the amorphous alumina barrier. Thus, Zheladnov *et al.* suggest that the presence of oxygen in the iron component of Fe–Al couples exerts a profound effect on observed rates of reaction diffusion in this system. This arises because the great affinity for oxygen by aluminium always generates amorphous alumina diffusion barriers at temperatures below 600°C. The work of Zheladnov *et al.* is in part corroborated by Bangaru and Krutenat,^[219] who also observed alumina induced diffusion effects in aluminium diffusion coated stainless steels. The influence of alumina at the reaction interface may explain many of the disparate results of previous studies of reaction diffusion phenomena in hot dip aluminised steel.

Other studies of solid state reaction diffusion in the Fe–Al system include those of Nishida and Narita,^[113] who interpreted the observed phase changes largely in terms of the accompanying volume changes, and also the study by Kwon and Lee^[112] of diffusion in Fe/ $\eta\text{-Fe}_2\text{Al}_5$ and $\eta\text{-Fe}_2\text{Al}_5$ /Fe couples. This last work resulted in an E_A value for the parabolic growth of $\zeta\text{-FeAl}_2$ of 118 kJ mol^{-1} in the temperature range 700–800°C. An analogous datum for $\theta\text{-FeAl}_3$ could not be computed since this phase did not form as a distinct stratum in the Fe/ $\eta\text{-Fe}_2\text{Al}_5$ couple, but was found as isolated precipitates in the aluminium matrix.

Kinetic data for interdiffusion in phases of the Fe–Al system has been presented in several studies. Diffusion in $\alpha\text{-FeAl}$ solid solution phases has been the subject of most investigations.^[220–223] Data for the diffusion of ^{59}Fe and ^{26}Al in both solid solution and intermetallic phases in the temperature ranges 600–1000°C and 520–630°C, respectively, have been obtained by Larikov and colleagues.^[142,154,155] These data, augmented with data from other sources^[30,224–226] have been used to compile the diffusion information given in Table 7.

Table 7 Diffusion data for Fe–Al system*

Phase or medium	Diffusion of Fe 600–1100°C		Diffusion of Al 520–630°C	
	$\ln D_0$	E_A , kJ mol^{-1}	$\ln D_0$	E_A , kJ mol^{-1}
$\theta\text{-FeAl}_3$	−12.59	101.4	4.018	199.4

The kinetics of iron diffusion in liquid aluminium have been studied by Eremenko and Nantanzon,^[177] Kato and Minowa,^[227] and Uemura.^[228]

In Type 1 aluminised steels, there is a dichotomy in research work on coating alloying behaviour. When used at temperatures below the liquidus temperature of the coating (about 580°C), retention of an outer luminous Al–Si coating is advantageous in terms of appearance and reflectivity properties. However, at higher temperatures, retardation of coating alloying is believed to encourage coating delamination, possibly through the formation of Kirkendall voids. Thus, research work has been aimed at inhibiting coating/substrate interdiffusion in those grades intended for use below the coating liquidus temperature, while expediting the reaction in grades intended for use above this temperature.

An early patent on alloying inhibition was that due to Batz and Thurman.^[229] These workers contend that a relatively very small increase in the free nitrogen content of aluminium clad low carbon steel markedly increases the temperature at which a significant rate of alloy layer growth was initiated on subsequent annealing. Using rimmed steels having very low concentrations of nitride forming elements such as aluminium and titanium, these workers showed that increasing the interstitial nitrogen content from about 0.003 to 0.010% increased coating alloying initiation temperature from 430°C to about 560°C. The effect of substrate nitrogen has subsequently been confirmed in several studies.^[119,200,201,203,204,230] An analogous study on the effect of substrate nitrogen during hot dipping has already been cited.^[85]

In the study by Hirose and Uchida^[203] the effect was investigated in Type 1 coated aluminium killed and low carbon rimmed steels, these latter grades containing varying amounts of interstitial nitrogen, while the former grades had no appreciable interstitial nitrogen content. No great differences in alloying rates between the grades were found above about 480°C. However, coating alloying effectively ceased in the rimmed steels at about this temperature. In the aluminium killed grades, measurable rates of alloying were recorded down to temperatures of about 360°C. Alloying in all grades was found to follow parabolic kinetics with E_A values of about 200 kJ mol⁻¹ apparent below the coating liquidus temperature of 580°C. Although differences in alloying behaviour were attributed to variations in substrate interstitial nitrogen content, it was also noted that the influence of nitrogen was nullified to some extent by increases in substrate carbon content. The nitrogen effect was thought to originate from formation of a nitride diffusion barrier at the steel/alloy layer interface, or possibly nitride formation within the alloy layer. Formation of an aluminium nitride diffusion barrier was originally proposed by Lainer *et al.*^[230] to account for similar observations of inhibition of reaction diffusion in specially prepared Fe/Al diffusion couples. These workers argued that formation of such a film was greatly favoured

because of the very large Gibbs free energy change which accompanies aluminium nitride formation (550 kJ mol⁻¹). The use of interstitial nitrogen as a special alloying addition to hot dip aluminised steel substrates is now patented technology.^[231]

The increasing demand for Type 1 aluminised steels capable of withstanding temperatures in excess of the coating liquidus temperature without scaling of the coating has led to the commercial introduction of “enhanced” Type 1 grades.^[13,73,232,233] All these materials have vacuum degassed, interstitial free, very low carbon substrates containing titanium and/or titanium and niobium additions. In each case, the titanium addition is in excess of that required to eliminate both carbon and nitrogen from solid solution. The stabilisation of interstitials as titanium nitride and carbonitride increases the rate of high temperature coating alloying and thus reduces the tendency to coating delamination.^[9,10,68,200–202,205,214,231,234–237] The desired property enhancement is achieved by promoting a rapid transition to α -FeAl solid solution which is claimed to preclude formation of voids at the coating/substrate interface.^[68,235]

Apart from improving high temperature coating adherence, the presence of titanium is also reported to improve oxidation and aqueous corrosion resistance of the substrate.^[9,10,68,205] The addition of niobium as a further microalloying constituent in some enhanced grades is aimed at improving the high temperature strength of the steel,^[9,205] though some workers argue that niobium vitiates the effect of titanium and re-establishes the tendency to destructive scaling when the material undergoes thermal cycling.^[68]

An alternative means of increasing the high temperature strength of hot dip aluminised steels and reduce the tendency to destructive scaling is claimed to be achieved by increasing the substrate manganese and silicon contents to about 1% and 0.6%, respectively.^[200,238] These additions are also claimed to improve oxidation resistance and have no influence on industrial aluminising kinetics.^[239,240] The mutually Interdependent effects of substrate carbon, nitrogen, and titanium on coating alloying kinetics in hot dip aluminised steels have been the subject of an ongoing study by Richards and Jones.^[119,171,241] Using a novel visible light reflectivity monitoring technique, these workers have investigated the coating alloying behaviour of a large number of both commercial and laboratory prepared aluminised steels. Alloying initiation temperatures for conventional Type 1 and Type 2 hot dip aluminised steels were found to fall in the range 400–450°C; increases in substrate interstitial nitrogen content up to 0.010% increased this temperature to about 520–540°C. Substrate additions of nickel were found to inhibit greatly the reaction, but the behaviour of aluminised Type 409 ferritic stainless steel (containing about 12%Cr and 0.2%Ni) was analogous to that of conventional Type 1 aluminised steel. Conversely, Type 1 aluminised interstitial free, titanium containing substrates were found to alloy rapidly at temperatures above 360–380°C. Evidently the removal of carbon and

nitrogen from solution expedites alloying, this result according with the influence of these elements on reactivity trends established in previous studies. All alloying reactions were found to approximate roughly to parabolic kinetics and, over narrow temperature ranges, to Arrhenius type temperature dependences: all calculated E_A values indicate relatively large dependences of greater than 120 kJ mol^{-1} . However, over the whole temperature range $360\text{--}700^\circ\text{C}$, such calculations were inappropriate since the dependences generally showed a shallow curvature.

Other studies relevant to coating alloying phenomena hot dip aluminised steels are those of Bedford and Boustead,^[110] Bangaru and Krutenat,^[219] and Dewing and Iyer.^[242] All three studies have suggested that austenitic substrates, or substrates with an addition of austenitising elements such as nickel, show lower rates of alloying than ferritic substrates. This result is in general agreement with previously cited studies which suggest the same effect operates during hot dipping.

CORROSION AND HIGH TEMPERATURE OXIDATION PROPERTIES

There are fundamental differences in the nature of the corrosion protection offered by zinc and aluminium coatings on steel. Zinc and zinc alloy coatings afford sacrificial (i.e. cathodic) corrosion protection of the steel base. In these materials, the greater negative electrode potential of zinc compared with iron, coupled with the porous nature of the corrosion products, ensures the constant preferential corrosion of the zinc coating. Thus, the coating is maintained at a potential anodic to the cathodic iron substrate. Advantageously, such protection usually extends to uncoated pores, cut edges, and the microfissures resulting from cold working of the material. With aluminium, primary corrosion protection of the steel base is afforded by formation of an impervious oxide barrier. The barrier property arises from the ability of aluminium to generate rapidly a very thin (typically 5–25 nm thick) and tenacious alumina surface film which is practically impermeable and insoluble in most common oxidising media. Thus, though more anodic than either iron or zinc, aluminium has only a very limited ability to protect steel cathodically since in most environments its preferential corrosion is essentially self-limiting.^[243]

Despite its importance, the volume of research on corrosion of hot dip aluminised steels is much more limited than that on either zinc or zinc–aluminium coatings. From the studies that have been conducted, it appears that in both industrial and rural environments hot dip aluminised steels offer markedly superior corrosion resistance than equivalent galvanised or zinc–aluminium coated steels;^[11,17,18,72,75,76,244–250] it is generally agreed that there is a comparative life factor relative to zinc of 2–7 in favour of aluminised steel. A greater discrepancy in life span can be anticipated in humid, sulphurous, or saline atmospheres.^[11,17,18,72,245] However, several workers point

out that, unlike zinc containing hot dip coating, bare spots, pores, and cracks are a possible source of failure in aluminised steels.^[13,17,18,72,248,251] This arises, it is reasoned, from a lack of cathodic protection by aluminium, often evidenced by red rust staining at asperities and uncoated cut edges. However, Dunbar^[72] and Coburn^[76] argue that such staining is basically a cosmetic problem, Dunbar pointing out that test panels exposed in an urban environment for over 40 years show no evidence of either coating failure at stained spots or coating delamination at cut edges.

The kinetics of atmospheric corrosion of Type 2 aluminised steel has been studied in detail by Legault and Pearson.^[251] These workers have shown that the weight losses (Δw) in aluminised steel over various exposure times (t years) in both industrial and marine environments can be expressed by an equation of the form

$$\Delta w = kt^n$$

where the empirical constants k and n are a measure of the short and long term susceptibilities of the material to corrosion.

Some workers suggest that the Type 2 material is slightly more corrosion resistant than Type 1^[11,14,72,76,249] though this is disputed elsewhere.^[16,72,244] Dunbar^[72] argues that Type 1 material has a slightly greater tendency to pitting corrosion, red rust staining, and coating darkening on atmospheric exposure. These imperfections are said to occur from a galvanic effect between the silicon rich inclusions in, and the aluminium matrix of, the outer coating. The unavoidable presence of solute iron in the outer coating has also been shown to exert a galvanic effect which can reduce its corrosion resistance.^[183,248] Dovey and Waluski^[16] have also reported premature darkening of Type 1 coatings on atmospheric exposure but claim that this does not reduce corrosion resistance. This assertion is supported by Rigo,^[252] who found that similar bluish darkening and/or red rust staining often associated with a surface 'patina' effect does not significantly compromise the overall corrosion resistance of aluminised wire. Dunbar suggests that these essentially superficial surface defects developed on atmospheric exposure can be eliminated by incorporating 0.2% Mg in the aluminising bath.

In saline and marine environments, disruption of the surface alumina film on aluminised steels has been shown to facilitate cathodic protection of the steel base at pores and cut edges.^[13,247,248,251,253–255] This effect probably arises from chloride ion sponsored dissolution of the alumina film.^[255] Higuchi and Asakawa^[253] have shown that in continuous salt spray testing the relatively higher rate of corrosion is associated with the formation of the bulky and porous corrosion products boehmite ($\gamma\text{-AlOOH}$) and bayerite ($\beta\text{-Al(OH)}_3$), while the lower rate of corrosion in alternate salt spray and humidity testing is associated with finer, amorphous corrosion products forming a more protective film. Agarwal and Legault^[256] have also established

that inherent coating thickness variations are an important feature of the corrosion performance of aluminised steels in standard salt spray testing.

Since a major market for the Type 1 material is automobile exhaust systems, much interest has been shown in its resistance to the combined effects of heat, exhaust gas condensates, and salt spray. Hooper *et al.*^[251] contend aluminised steel only extends the average lifetime of an exhaust system from 1.5 to 2.25 years while Cannings^[258] suggests an additional 6 months use compared with mild steel. It appears that failure is initiated at uncoated cut edges^[259,260] or welded seams where the coating has been destroyed.^[257] Partly to overcome the problem of the lack of cathodic protection at cut edges, some workers have advocated the use of Zn–Al hot dipped coated steels in exhaust systems^[261] though Sumiya *et al.*^[262] dispute this, finding that all zinc containing coatings were prone to rapid exhaust gas condensate corrosion particularly after alloying at high temperature; pure zinc and Zn–5Al coatings were deemed totally unsuitable for this reason.

At temperatures below the temperature at which coating alloying occurs (*see* the section “Elevated temperature reaction diffusion in hot dipped aluminised steels” above), oxidation of the outer aluminium or Al–Si coating is relatively unimportant. At these temperatures, even when exposed to fairly aggressive environments, the ability of aluminium to generate a protective alumina film means that coating degradation proceeds relatively slowly. However, on exposure to temperatures in the range 360–500°C, the ability of an alloyed coating produced by reaction diffusion to protect the steel base from oxidation becomes critically important.

The general principles governing the oxidation kinetics of diffusion coatings have been discussed by Whittle.^[263] Assuming parabolic oxidation kinetics, Whittle emphasised that a low rate of alloying is not beneficial to oxidation resistance even though it might be expected to allow a greater concentration of the oxidation resistant component to reside at the material surface. This arises because a low diffusion coefficient of the oxidation resistant component also reduces the rate at which a protective oxide film can be formed at the surface. Hence, in such a system, the surface concentration soon drops below the critical level required to form a continuous oxide barrier. This reasoning probably accounts for the previously cited claims that while the primary purpose of titanium substrate additions is to expedite coating alloying, reduce void formation, and hence reduce destructive scaling, it has the additional benefit of improving the oxidation resistance of the alloyed coating.^[9,10,68,200,204,205,264,265] Gibson *et al.*^[9] claim niobium has an analogous effect.

Ideally, the oxidation of aluminised steel should proceed according to a parabolic rate law by volume ionic diffusion across the outer alumina barrier. Parabolic oxidation kinetics have been verified experimentally by a number of workers.^[68,118,172,265,266] Similar oxidation behaviour has been

observed in steels aluminised by other means.^[267,268] In hot dipped aluminised steels, the only exception to this trend is in the work of Chess,^[269] who found that rate data best fitted linear equations. This anomalous result was attributed to oxidation of cut specimen edges despite coating with inert material. A similar problem was overcome by Hughes and Thomas^[172] by utilising completely coated laboratory prepared specimens. However, this method cannot be used in assessing commercial materials which of necessity must always be severed from large parent sheets. An alternative correction technique^[9,68,265] has involved separating the contributions of coated and uncoated areas by testing samples with varying coated/uncoated area ratios. By assuming independent oxidation rates for the two surfaces and extrapolating observed weight gains to zero, uncoated area edge corrected data has been obtained.

The advantage of thick initial coatings has been demonstrated practically^[68,265] by comparing the oxidation behaviour of commercially produced hot dip aluminised steels with 25 and 40 µm coatings. The thinner coated material showed evidence of rapid oxidation after exposure for 400 h at 816°C; similar behaviour in the thicker coated material was observed after 1000 h. This was attributed to the inability of the former material to sustain a continuous protective alumina film because of an initially smaller reservoir of aluminium at the surface. Elaborating the oxidation failure mechanism of aluminised steels, these workers argue that the appearance of isolated iron oxide nodules at gaps in the alumina film does not necessarily herald immediate catastrophic failure of the material. Such gaps are often healed by the formation of an underlying layer of alumina which isolates the nodule from the substrate. However, as the density of nodules increases, they coalesce and grow laterally, eventually isolating the aluminium rich zone from the substrate: total rapid failure then follows. As these authors point out, localised failure often results from variations in the total coating thickness of the as produced material. Obviously, spalling of the coating (*see* the section “Elevated temperature reaction diffusion in hot dipped aluminised steels” above) can also cause localised or total coating failure. The effect of substrate chromium additions on the heat and corrosion resistance of hot dip aluminised steels was first investigated by Hughes and Thomas.^[172]

Recent work has focused attention on the use of aluminised chromium containing steels in automobile exhaust systems and similar high temperature very corrosive environments. In this context the behaviour of a range of aluminised, low carbon steels with chromium contents up to about 18% and containing various microalloying additions of titanium, manganese copper, silicon, and nickel have been reported.^[9,118,200,234,238,253,264,270–274] Clements^[118] has investigated the oxidation and corrosion behaviour of a series of Type 1 aluminised steels with chromium contents in the range 2–9%. He concludes that a 2%Cr composition offers the best oxidation resistance on prolonged exposure at 750°C, but that the higher chromium containing

materials afford better ambient temperature corrosion resistance in synthetic car exhaust condensate solution.

Without an accompanying chromium content, other elements claimed to improve the oxidation resistance of Type 1 titanium stabilised, low carbon steels are a combined addition of manganese, phosphorus, silicon, and boron^[234] and manganese and silicon.^[200] Higuchi *et al.*^[273] dispute the beneficial effect of silicon and claim additions of phosphorus in excess of 0.1% decrease oxidation resistance.

SURFACE PROPERTIES

Aluminised steels are frequently used in an unpainted condition where an ability to reflect a high proportion of visible and infrared radiation is an important attribute. Although hot dip aluminised steels are frequently quoted as having high light and heat reflectivities the only optical data available are due to Richards^[119] and Hart and Townsend.^[275]

Comparing the total reflectivities of Type 1 aluminised steel and Galvalume in the visible and near infrared range (i.e. in the wavelength range 500–2500 nm) Hart and Townsend found that the aluminised material reflected about 70% of incident radiation whereas the Zn–Al coated material reflected about 90%. Similar data were obtained in the infrared range at a fixed wavelength of 3000 nm. In an attempt to assess the practical consequence of the difference in infrared reflectivities, the surface temperatures of panels of each material were measured when located near a heat source. On exposure, the temperature of aluminised steels was found to be substantially greater than that of Galvalume. Following Auger spectroscopy analyses of the surfaces, the apparently inferior reflectivity of aluminised steels was attributed to the presence of a silicon rich zone in the surface of the material.

Similar experimentation to that outlined above has subsequently been performed by Richards^[119] on Type 1 and Type 2 aluminised steels and Galvalume. Contrary to the results of the previous study, in the visible–near infrared range extending from 500 to 1800 nm, and at the higher wavelength of 3000 nm, the Type 1 and Galvalume materials were found to have roughly equivalent reflectances. On average, about 50–60% of total incident radiation was reflected in the visible and near infrared, and about 75% at 3000 nm. The Type 2 material had consistently higher reflectivities of about 75 and 90%, respectively.

Panel temperature experiments on the three materials suggested that the ability of coated steels to conduct heat when adjacent to a thermal source was more a function of coating thickness than composition, since substantial differences in temperature attainment were not apparent with different coatings of equivalent thickness. Further, X-ray photoelectron spectroscopy surface analyses of all three compositions suggest that the segregation of silicon at the surface of Type 1 materials established by Hart and Townsend is also present in Galvalume and even

Type 2 aluminised steels, despite this latter grade having a nominally silicon free coating composition.

Other information on the reflectivity of aluminised steels is purely empirical, it being generally agreed that the 'lustre' of the Type 2 material is superior to that of the Type 1 material.^[11,16,77] The lustre of the Type 1 grade is claimed to improve with small additions of titanium, chromium, boron, molybdenum, or zirconium to the melt.^[16,77] Unlike zinc containing coatings where careful pretreatment is essential for the successful application of organic coatings, the tenaciously adherent surface alumina film makes aluminised steel an ideal substrate for further coatings of paints, resins, lacquers, and heat resistant enamels. Sano *et al.*,^[276] for example, have developed a novel silicone modified polyester coating which is claimed to enhance resistance to car exhaust condensates considerably, while Cholet and Spehner^[277] have described in detail the use of aluminised steels as enamelling substrate.

Metallurgy of Quenching Aluminum Alloys

Ralph T. Shuey and Murat Tiryakioğlu

Department of Engineering, Robert Morris University, Moon Township, Pennsylvania,
United States

Abstract

The present authors have collaborated since 2000 on revitalizing and extending the technology for metallurgical aspects of quenching heat-treatable aluminum alloys, which had been developed by Dr. James T. Staley, Sr. starting with Ref. [57] and continued until his retirement from Alcoa three decades later. Our objective in this chapter is a concise and current overview of what came before us and what we have added. For this we have surveyed the open literature as well as Alcoa files going back into the 1940's, excluding any details that might still be considered proprietary. We suppose our reader to be soundly grounded in metallurgical engineering, but not necessarily with any knowledge specific to aluminum. We have excluded the topic of quench-aging, the combination of quenching and aging into a continuous process, as a substantive survey would be heavy in proprietary concepts and sophisticated metallurgy. We have also excluded thermal and mechanical aspects of quenching aluminum alloys, as well as equipment and quenchants used in fabrication of aluminum products. On these topics much of the information presented elsewhere in this volume, is generally applicable to aluminum. We conclude with our views on what has been established, how to use it, and where to go next with the techniques pioneered by our mutual mentor, Dr. James T. Staley.

INTRODUCTION TO ALUMINUM

Occurrence and Use

Aluminum comprises about 8 percent of the atoms in earth's crust. It is found in most rocks, clay, soil and vegetation. Natural occurrence is only as compounds with oxygen and other elements, never as in metallic form. The availability of products based on aluminum depends on two chemical processes developed in the late 19th century. In the *Bayer* process, alumina (Al_2O_3) is extracted from bauxite - rock in which aluminum hydroxides have been highly concentrated by weathering. In the *Hall/Héroult* process, alumina is dissolved in molten cryolite (Na_3AlF_6), and the solution is electrolyzed to obtain aluminum metal. This "commercial purity" aluminum contains minor impurities of Si, Fe and other elements. Only for specialized low-volume applications is there further refinement. About a third of the cost of aluminum produced from ore ("primary" aluminum) is the energy for the Hall/Héroult process. Current aluminum products use a blend of primary and recycled aluminum.

Aluminum is distinguished among metals by its low density, high surface reflectivity, high electrical and thermal conductivity. Aluminum and its alloys can be cast, formed, machined and joined by many techniques. They accept a wide variety of finishes. Good corrosion resistance results from a continuous film of aluminum oxide that grows rapidly on a nascent aluminum surface

exposed to air. An excellent general survey of aluminum technology is Ref. [3].

Strengthening Mechanisms

Figure 1 is a sketch of stress vs. strain in tensile testing of an aluminum alloy. Above the yield strength, aluminum deforms plastically, but increasing stress is required for further deformation. On an atomic scale, plastic deformation is by glide of dislocations along certain crystallographic planes of the fcc (face-centered-cubic) crystal structure. In a hypothetical perfect aluminum crystal, the stress to initiate such deformation is negligible. The yield strength of aluminum in use is due entirely to atomic and microstructural obstacles to dislocation glide. Figure 2 indicates the main types of such obstacles.

Dislocations are produced mainly by prior plastic deformation. Hence, resistance to deformation results from deformation itself. Strength due to grain boundaries may be increased by special processing to reduce grain size. Strengthening by solute requires alloying with an element having high solubility in aluminum. Strengthening by particles depends significantly on particle diameter, as sketched in Fig. 3. The smallest possible particle would be a single atom (solute strengthening). Clustering the atoms into particles increases the resistance to dislocation glide. However at very large particle size, the resistance again decreases. This is because at large particle spacing the

Fig. 1 Engineering Stress vs. Strain in tensile testing of aluminum alloy

Fig. 2 Types of strengthening mechanisms (obstacles to dislocation glide)

Fig. 3 How strengthening by alloying elements depends on particle diameter. Greatest strength is with particles a few nanometers in size. Least strength is with most of the element in particles a micrometer or larger

gliding dislocations can bypass the particles. Strengthening in that case is given by the Orowan equation,

$$\Delta\sigma = K\mu \frac{b}{\lambda} \quad (1)$$

in which

- $\Delta\sigma$ increase of yield strength
- K dimensionless coefficient, of order unity
- μ shear modulus of aluminum (26 GPa)
- b interatomic distance (2.84×10^{-10} m)
- λ spacing between particles

Maximum strengthening from a given number of solute atoms may be at particle diameter only tens of atoms. Strengthening is negligible for particles a micron or larger.

Strengthening particles are generally intermetallic compounds of aluminum and one or more alloying elements. The production of strengthening particles differs according to whether or not the particles can dissolve in aluminum at temperature below the solidus (lowest temperature of partial melting). Insoluble particles are commonly termed dispersoids, and the corresponding result dispersion strengthening. Strengthening by soluble particles is commonly termed precipitation hardening, and the compositions for which this is possible are called heat-treatable alloys. The heat treatment comprises three steps:

- Solutionizing (or solution treatment).
- Quenching.
- Aging (natural and/or artificial).

The present chapter focuses on quenching, which is one step in producing one class of aluminum alloys. Information from the larger scope of aluminum metallurgy is brought in only as deemed useful in dealing with quenching of aluminum.

Generally the greater the yield strength, the lower the ductility (amount of plastic strain before failure). Among the various mechanisms for strengthening aluminum, precipitation-hardening generally produces the highest strength, and correspondingly the lowest ductility. For example, aluminum 99.99% pure has a tensile yield strength about 10 MPa (1.4 ksi) and elongation of 50%. By contrast, alloy 7075-T6, introduced during WWII for aircraft production, has a tensile yield strength of about 500 MPa (73 ksi) and an elongation of about 10%.

Hatch^[26] and Davis^[13] offer rich detail about production and properties of many specific aluminum alloys. Nembach^[40] presents fundamentals of particle strengthening. Kocks, Argon and Ashby^[33] analyze formally how different strengthening mechanisms combine and behave over time and temperature.

Alloy Designations

Compositions of wrought aluminum alloys are registered with a 4-digit code, by international agreement.^[2] Table 1 gives the criteria distinguishing the various alloy series. “Wrought” means that the particular alloy is available primarily in semi-fabricated forms resulting from rolling, forging, extrusion, and/or drawing. These “working” operations are preceded by alloying and then casting. Interspersed may be thermal treatments acting to modify solute distribution, grain structure, dislocation density, and/or internal stress. The customer for the semi-fabricated shape may perform forming and/or joining operations for the final use. However, the material properties are largely determined by composition and thermo-mechanical operations at the mill.

Table 1 International grouping of wrought alloys by Wt% alloying elements

Series	Criterion
1xxx	Total alloying elements not more than 1 wt%
2xxx	Cu most abundant by wt%
3xxx	Mn most abundant by wt%
4xxx	Si most abundant by wt%, and wt%Mg < 0.5 wt%Si
5xxx	Mg most abundant by wt%, and wt%Mg > 4.46* wt%Si
6xxx	Mg or Si most abundant by wt%, and 0.46 wt% Si < wt%Mg < 4.46 wt%Si.
7xxx	Zn most abundant by wt%
8xxx	Most abundant other than Cu, Mn, Mg, Si, Zn.

Table 2 Aluminum Association (AA) grouping of foundry alloys

Series	Criterion
1xx	Total alloying not more than 1 wt%
2xx	Cu most abundant by wt%
3xx	Si most abundant by wt%, significant Cu and/or Mg
4xx	Si most abundant by wt%, minimal Cu and Mg
5xx	Mg most abundant by wt%
6xx	Unused
7xx	Zn most abundant by wt%
8xx	Sn most abundant by wt%

Although Russia is now a signatory of the international accord for wrought aluminum alloys, most of the alloys developed by the former USSR are still known only by a distinct USSR 4-digit system. Only some of the USSR alloys have close equivalents in the international system.

There is no international system for registration of alloy compositions intended for casting to near-final shape. Many foundry (casting) alloys in general use are registered according to the system indicated in Table 2.^[1] Some foundry alloys have a designation assigned by the Society of Automotive Engineers.^[46]

There are several reasons why the ensemble of compositions used for foundry products differs from that used for mill products. One is that foundry products cannot use working to modify grain structure or increase dislocation density. Another is that casting to shape generally requires alloys with good fluidity and resistance to hot tearing. Most commonly used alloys contain Si beyond the solubility limit, sufficient to form eutectic particles. The Si addition improves alloy castability significantly. Pure aluminum contracts approximately 7% upon solidification, making it quite difficult to cast. The addition of Si reduced this contraction because Si expands upon solidification, partially making up the volumetric decrease in aluminum matrix.

Heat-Treatable Compositions

For a composition to be heat-treatable, it must include one or more alloying elements in amounts which exceed solubility at room temperature, but which can be dissolved at high temperature. Figure 4 shows this schematically. Following are the changes during the three main steps of heat treatment:

1. **SHT:** Temperature is raised nearly to a eutectic temperature, which substantially dissolves this alloying element into solid aluminum.
2. **Quench:** Temperature is rapidly dropped to near room temperature, leaving the element in unstable solid solution.
3. **Aging:** With appropriate time and temperature, the element comes out of solution to form strengthening particles.

The increase of strength during aging is the amount of particle strengthening, minus the solute strengthening of the amount precipitated. As sketched in Fig. 3, for a maximum effect, the particle size should be in a certain size range of order of nanometers. For a given size, particle strengthening is proportional to the amount precipitated. This amount is indicated in Fig. 4 as the difference between amount solutionized and solubility at the aging temperature.

Only a small number of compounds have been found capable of precipitation strengthening aluminum with commercial success. Table 3 provides a list of such phases. Since they occur only as very fine particles, the exact composition and crystallographic structure becomes known by fundamental studies only after commercial use has been established. Least understood of the commercially successful precipitation strengtheners is the quaternary phase denoted in Table 3 as Q'' .^[10,69]

Among the wrought alloys, essentially all those in the 2xxx, 6xxx, and 7xxx series are produced with precipitation strengthening, hence with quenching as part of the fabrication sequence. Likewise essentially all foundry alloys of the 2xx,

**Fig. 4** Schematic phase diagram of a heat-treatable alloy, showing temperature ranges for solutionizing and for aging, and showing amount of solute precipitated during aging

Table 3 Phases for precipitation hardening, and the alloy series in which they appear

Phase	Elements	Nominal formula	Wrought series	Cast series
θ'	Al-Cu	Al_2Cu	2xxx	2xx
S'	Al-Cu-Mg	Al_2CuMg	2xxx	2xx
T_1	Al-Cu-Li	Al_2CuLi	2xxx(Li)	—
β''	Mg-Si	Mg_5Si_6	6xxx	3xx
Q''	Al-Cu-Mg-Si	??	2xxx, 6xxx	3xx
η'	Al-(Cu)-Mg-Zn	??	7xxx	7xx

Table 4 Phases appearing as quench precipitates

Phase	Nominal formula	Wrought series	Cast series	Q_p , kJ/mole
θ	Al_2Cu	2xxx	2xx	133
S	Al_2CuMg	2xxx	2xx	130
T_1	Al_2CuLi	2xxx(Li)	—	132
T_B	$\text{Al}_7\text{Cu}_4\text{Li}$	2xxx(Li)	—	133
β	Mg_2Si	6xxx	3xx	120
β'	Mg_9Si_5	6xxx	3xx	120
Q	$\text{Al}_4\text{Cu}_2\text{Mg}_8\text{Si}_7$	2xxx, 6xxx	3xx	126
M	$\text{Mg}(\text{Cu}, \text{Zn})_2$	7xxx	7xx	117

3xx, and 7xx series are heat-treatable. However precipitation hardening may be foregone in some specific situations.

METALLURGICAL CHANGES DURING QUENCH

Precipitate Phases

The most importance metallurgical change during quench is loss of solute to quench precipitates which are essentially non-strengthening. The strength attained after aging is

reduced in proportion to the solute lost to precipitates during quench.

Table 4 lists some phases commonly observed to precipitate during quench. There is no consistent relation to the corresponding hardening phases listed in Table 3, other than involving the same alloying elements:

- S' formed during aging and S formed during quench have the same composition Al_2CuMg , and the same crystal structure.
- θ' formed during aging and θ formed during quench both have composition about Al_2Cu , but different crystal structures.
- β'' formed during aging has composition Mg_5Si_6 , the quench precipitates β and β' have compositions Mg_2Si and Mg_9Si_5 respectively.

In most cases the quench precipitate is a “stable” phase, meaning it appears in the equilibrium phase diagram. The main exception is β' - Mg_9Si_5 , which is not a stable phase.

Detailed fundamental studies of quench precipitates have often lagged by decades the development of a new heat-treatable alloy. Table 5 lists the phases observed to precipitate during quench in some commercial alloys. The compositions shown are only approximate, and include only those elements involved in solute loss to quench precipitates. Quench precipitates were generally documented early for USSR alloys.^[6,14,16]

Only exceptionally is precipitation during quench by growth of an existing particle, rather than nucleation of new particle. The lower-price grades of high-solute wrought alloys such as 2024, 6061 and 7050 are not completely solutionized in practice. Growth on residual particles during quench can be detected metallographically, but the effect on properties is insignificant, mainly because of the low number of particles. However, in high-silicon foundry alloys, eutectic silicon particles exist during quench in high number and volume. Here a detailed analysis may include growth during quench.^[62]

Table 5 Phases precipitating during quench in selected alloys

Precipitation Sites

Non-strengthening quench precipitates nucleate heterogeneously, that is, at defects of the aluminum crystal structure. The energy barrier to nucleation is effectively reduced by consuming some of the energy stored in the defect. Following are some examples:

- Grain boundaries are always sites of precipitation. Figures 5 and 6 are SEM images of Mg_2Si and M-phase respectively precipitated on grain boundaries. Figure 7 is a TEM view of a grain boundary in material close to that in Fig. 6.
- Subgrain boundaries, which subdivide unrecrystallized grains in deformed aluminum, act similarly but with a higher energy barrier to nucleation, consequent to the lower deformation energy stored in the boundary. A decorated subgrain boundary is barely resolved in Fig. 6.

Fig. 5 SEM image of Mg_2Si precipitates on grain boundaries in 6260-T4 (Shuey and den Bakker;^[49] Courtesy of Alcoa)

Fig. 6 SEM image of M-phase precipitates at grain boundary in alloy 7085-T7, (Ralph T. Shuey, Courtesy of Alcoa)

Fig. 7 TEM image showing plate-shaped M-phase grain-boundary quench precipitates and η' aging precipitates. Note PFZ (precipitate-free-zone) along grain boundary, where aging precipitates are absent due to local depletion of solute by prior formation of grain-boundary precipitates. Alloy 7055-T7. Fig. 8 SEM image of Mg_2Si precipitates on Si eutectic particles in D357 aluminum casting alloy. The specimen was held for 10,000 s at 450°C

Source: From (Tiryakioğlu and Shuey, 2007).

- Constituent particles (particles formed during casting) can be effective sites for nucleation of quench precipitates. In many wrought alloys this is unimportant because of the low number of constituent particles, and the large distance between them. Figure 8 shows an opposite extreme, abundant Mg_2Si nucleated on eutectic Si in a foundry alloy.
- In wrought alloys, Mn, Cr and/or Zr are commonly added to form dispersoids during the initial heatup

Table 6 Phases common as dispersoid particles

after casting. These dispersoids are intended to control microstructure in response to deformation, but they are also sites for nucleation of quench precipitates. Table 6 lists the most common dispersoid phases. Figure 9 is an example of quench precipitate nucleated at a dispersoid.

- Individual dislocations can act as nucleation sites, but the energy barrier is higher yet than for subgrain boundaries. Figure 10 is an example of precipitates nucleated on a dislocation. Dislocation density is low during quench, because “recovery” of strain energy

during solutionization sweeps most dislocations into subgrain or grain boundaries. Hence, dislocations are never the dominant site of quench precipitates.

Classical Nucleation Theory

The rate at which new particles appear during quench can be described by classical nucleation theory (CNT). Research reviews are by Refs. [11] and [45]. An accessible textbook is Ref. [41]. These expositions generally present first the theory for homogeneous nucleation, then adapt to some specific heterogeneous geometry, particularly nucleation at grain boundaries as analyzed by Ref. [8]. Following is an outline for classical nucleation at a generic heterogeneous site. This is to help clarify the fundamental basis for the numerical models of quench sensitivity presented in “Numerical Models” section below.

At the solvus temperature T_s , the molar Gibbs energy G is the same for atoms in solution or in precipitate phase. At temperature $T < T_s$, the precipitate is lower in G than the solution by the amount

$$\Delta G = \Delta H \frac{T_s - T}{T_s} \quad (2)$$

where ΔH is the molar enthalpy (binding energy) of assembling the precipitate from solution. Although the thermodynamic driving force for precipitation increases linearly with undercooling ($T_s - T$), a finite undercooling is needed before any particle appears. The barrier is the energy of interface between particle and matrix, which is relatively more important as the particle is smaller. A generic relation between net energy change Q and particle volume V is

$$Q = \frac{3}{2} K_N \cdot V^{2/3} - \frac{\Delta G}{V_M} \cdot V \quad (3)$$

where K_N is a parameter with dimensions of energy per area (J/m^2), and V_M is the volume per mole (about 10^{-5}m^3). Eq. 3 is sketched in Fig. 11. The particle can graduate from “nucleation” to “growth” if volume exceeds the critical value:

$$V^* = \left(K_N \cdot \frac{V_M}{\Delta G} \right)^3 \quad (4)$$

The energy barrier to reaching this critical size is:

$$Q^* = \frac{\Delta G}{2} \frac{V^*}{V_M} = \frac{1}{2} K_N^3 \left(\frac{V_M}{\Delta G} \right)^2 \quad (5)$$

The CNT expression for nucleation rate is:

$$\frac{dN_p}{dt} = \frac{N_s - N_p}{\tau} \cdot \exp\left(\frac{Q_D}{RT}\right) \cdot \exp\left(-\frac{Q^*}{RT}\right) \quad (6)$$

Fig. 11 Energy Q to create a particle from solute, as a function of particle volume V , at finite undercooling (Schematic)

- N_s density of nucleation sites ($1/m^3$)
- N_p density of particles ($1/m^3$)
- τ an atomic vibration time (sec)
- Q_d molar activation energy for diffusion (kJ/mol)
- R gas constant, 0.0083 kJ/(mol-K)

Analytic expressions for the vibration time τ appear in the references just cited, but detail is not critical. The activation energy Q_d can be calculated from the precipitate composition and the known diffusivities of individual solute elements, or the principle that reciprocal diffusivity in the equivalent pseudo-binary system given by the reciprocal diffusivities of individual solute elements, weighted by their atomic fraction in the precipitate phase. This principle is derived from approximate solute for the steady-state solute diffusion to the particle. Representative values are included in Table 4. Note that variation between activation energies is slight, for the tabulated precipitates.

The nucleation rate in Eq. 6 is extremely sensitive to the parameter K_N , which appears cubed then exponentiated. Thus in practice numerical values have to be determined

by fitting to observed nucleation rates. This is discussed further in “Numerical Models” section below, on numerical models of quench sensitivity. For homogeneous nucleation, as detailed in the cited references, K_N would have the value

$$K_N = 2\gamma \cdot \left(\frac{4\pi}{3}\right)^{1/3} \approx 3.22 \cdot \gamma \quad (7)$$

where γ is the interface energy between particle and matrix. Some examples of homogeneous nucleation in aluminum have $\gamma \approx 0.03$ J/m², corresponding to $K_N \approx 0.1$ J/m². For the quench precipitates described above, the interface energy is $\gamma \approx 0.25$ J/m², and the barrier Q^* is too high for homogeneous nucleation. Heterogeneous nucleation of quench precipitates, as shown in Figs. 5–10, is possible because some energy of the nucleation site is consumed in creating the particle, which lowers to K_N well below the value given in Eq. 7.

Temperature Dependence of Nucleation

Substituting from Eq. 2 into Eq. 4 gives dependence of linear size $V^{*-1/3}$ on temperature:

$$(V^*)^{1/3} = K_N \left(\frac{V_M}{\Delta H}\right) \frac{T_s}{T_s - T} \quad (8)$$

Thus the size of the nucleus decreases inversely with undercooling. The lower the temperature of nucleation, the finer the precipitation. Equation 8 is plotted in Fig. 12 for representative values.

Fig. 12 Temperature Dependence of Nucleation Rate and Nuclear Size, from Eqs. 6 and 8, with representative parameter values

Substituting from Eq. 2 into Eq. 5 gives the dependence of nucleation barrier on temperature:

$$Q^* = \frac{1}{2} K_N^3 \left(\frac{V_M}{\Delta H} \right)^2 \cdot \left(\frac{T_s}{T_s - T} \right)^2 \quad (9)$$

Thus the energy barrier decreases inversely with the square of undercooling. The consequence for nucleation rate is shown also in Fig. 12. For some tens of degrees below the solvus, nucleation rate is numerically zero – the energy barrier Q^* is too high. Then once the barrier is low enough, nucleation rate rises rapidly with increased undercooling. Then with further decrease of temperature, nucleation rate falls because of slow diffusion.

Size is the essential difference between aging precipitates and quench precipitates. The aging precipitates are near the size for peak strengthening (Fig. 3), while the quench precipitates are generally an order of magnitude larger. As apparent in the above discussion of Tables 3 and 4, the size difference is not due to any difference in the compounds formed. Rather the size difference originates with nucleation: the aging precipitates nucleate in much higher number per volume than do the quench precipitates. The biggest factor in this is the temperature at which nucleation occurs. The aging precipitates are nucleated somewhere between room temperature and 190°C (375°F), dependent on alloy. The quench precipitates are nucleated in a range of higher temperatures, between the aging and solutionizing temperatures. This range appears as a gap in Fig. 4.

Factors in Solute Loss

The thicker the product, or the lower the heat-transfer to the quenchant, the more solute is lost to precipitates during the quench. However for a given quench rate, there are a number of metallurgical factors in solute loss.

One factor is solvus temperature. The higher the solvus temperature, the higher the temperature range at which quench precipitates nucleate, the faster the diffusion of solute to the precipitates. For the same quench rate, a greater proportion of solute is lost in alloy 7055 than in 7085, or in alloy 6061 than in 6063, because of the higher solvus.

Another factor in solute loss is type of dispersoid. In 7xxx alloys the Zr-dispersoid presents a higher barrier to nucleation of M-phase than does the Cr-dispersoid.^[12,27] The interface between aluminum and the Al_3Zr dispersoid as formed is coherent (atomic spacing matched between crystal lattices), whereas the interface with the $(Al,Zn)_{18}Mg_3Cr_2$ is incoherent (disordered on atomic scale). A coherent interface has a lower energy, hence less to offset the energy of new interface with M-phase.

Prior strain can increase solute loss during quench, because the deformation energy can remain available to offset the interface energy of new precipitate. In deformation

of 7xxx alloys with Zr-dispersoids, each passage of a gliding dislocation through an Al_3Zr dispersoid converts the interface to incoherent, which reduces the energy barrier to nucleation of M-phase at the dispersoid.^[32]

Lower temperature of dispersoid formation (lower temperature of ingot homogenization) can increase solute loss during quench. This is familiar in 6xxx alloys,^[4,7,43] where the $Al_{12}(Mn,Cr)_3Si$ dispersoid is an efficient nucleation site for β' quench precipitate.^[36] At lower formation temperature there are more dispersoids and hence more solute loss.

In 2xxx and 7xxx-Zr alloys, lower temperature of dispersoid formation can increase solute loss by a different mechanism. In these cases, solute loss at dispersoids is secondary to solute loss at grain or subgrain boundaries. If the product is partially recrystallized during quench, lowering the temperature of dispersoid formation will increase the boundary area and thereby increase solute loss.

Increasing alloy Mn has an effect similar to that just described for lowering temperature of dispersoid formation. Increasing alloy Mn increases supersaturation at dispersoid precipitation, hence the number of dispersoid particles. The corresponding effect for amount of Cr or Zr is not so practical, because higher amounts of these elements lead to “coarse constituents” rather than more dispersoid-forming element in solid solution after casting.

QUENCH EFFECT ON PROPERTIES

Temperers

The beneficial effect of quenching on properties is realized only upon aging. Table 7 gives the standard “temper” designations for the various sequences of operations which may follow quench. However not all temperers are appropriate for all alloys. Rather, for each alloy series only a few temperers are commercially practical. Table 7 indicates the main matches.

The temperers T3, T8, and T9 involve cold work, hence are only for wrought products, not castings. With temperers T3 and T8 the cold work is between quenching and aging, so that the aging occurs in presence of a high density of dislocations. In 2xxx alloys this is a benefit, because all the hardening precipitates (S' , θ' and T_1 in Table 3) nucleate on dislocations. The speed of age-hardening, and the maximum strength attained, increase in proportion to the plastic strain applied between quench and age. On the contrary, in 7xxx alloys the presence of dislocations has a negative effect on aging response. The η' hardening precipitates in 7xxx alloys grow from small atomic clusters whose formation is inhibited by presence of dislocations. In 6xxx alloys, dislocations do not have a strong effect positive nor negative on age-hardening.

Table 7 Temper designations for age-hardening after quench

Temper	Aging	Wrought	Cast
W	No Aging (unstable temper)	—	—
T3	Cold Worked, then Naturally Aged	2xxx	—
T4	Naturally Aged	2xxx	2xx
T6	Artificially Aged to Peak Strength	6xxx, 7xxx	3xx
T7	Artificially Aged past Peak Strength	7xxx	2xx, 3xx
T8	Cold Worked, then Artificially Aged	2xxx	—
T9	Artificially Aged, then Cold Worked	2xxx, 6xxx	—

Note: Defined tempers T1, T2, T5, and T10 are not included, as they do not include quench.

The high solute content of heat-treatable alloys as-quenched (W temper in Table 7) is metallurgically unstable at room temperature. Within hours, the solute atoms start forming small clusters. This “Natural Aging” does have a strengthening effect, but it is only in certain 2xxx alloys that the effect is large enough and stable enough to be commercially useful without a following “Artificial Aging” at elevated temperature (usually in range 120°C – 190°C).

Measures of Solute Loss

As detailed in “Metallurgical Changes during Quench” section above, the most importance metallurgical change during quench is loss of solute to quench precipitates. This can be quantified several ways:

Electrical resistivity (ρ) is an inexpensive, direct measure of solute retained in the metal. At 20°C the resistivity of aluminum ($\mu\Omega\cdot\text{cm}$) with elements in solution is

$$\rho = 2.655 + \sum W_i K_i \quad (10)$$

where the sum is over solute elements, W_i is the wt% of each in solution and K_i is a tabulated resistivity coefficient. A few coefficients are in Table 8, more are tabulated by Ref. [63]. For example, if the only solute were 5.0 wt% Cu, the resistivity would be $\rho = 2.655 + 5 \times 0.54 = 5.355 \mu\Omega\cdot\text{cm}$. Electric measurement on aluminum are usually reported as conductivity in IACS% (International Annealed Copper Standard). This is related to resistivity by:

$$\text{IACS}(\%) = \frac{172.41}{\rho} \quad (11)$$

Thus the 5% Cu in solution reduces conductivity to 32.2% IACS.

A poor quench gives a low resistivity (high conductivity) as-quenched. A potential pitfall with use of resistivity

Table 8 Resistivity coefficients of solute in age-hardening precipitates. Increase in resistivity $\mu\Omega\cdot\text{cm}$ per wt% in solution

Cu	Mg	Si	Zn	Li
0.344	0.54	1.04	0.01	3.31

**Fig. 13** Reduction of Electrical Conductivity due to natural aging after quench, for three alloys

Source: From Hatch,^[26] p. 177.

is the instability of W-temper. Solute clustering during natural aging increases resistivity quickly, the relation being somewhat like that shown in Fig. 2 for the resistance of particles to dislocation glide. The increase in electrical resistivity (decrease in electrical conductivity) during natural aging is shown in Fig. 13 for three commercial alloys. Resistivity after aging is a monitor for the aging process, rather than the quench process. Therefore, electrical resistivity should be measured immediately after the quench if the data will be used to assess the quench.

Hardness tests can be used to monitor solute loss in quench. Due to high spatial resolution, hardness is sensitive to non-uniformity of quench. A poor quench gives low hardness, whether the measurement is made as-quenched or after aging. Measurement after aging is preferred, because the effect of a given solute increment is greater and more repeatable. Vickers and Meyer hardness values are more linearly related to solute than are Rockwell or Brinell hardness.

Tensile yield strength (σ_y) changes linearly with solute content in the alloy. Figure 14 shows this linear relationship in a suite of 7XXX alloys. Similar results were reported for 6XXX alloys.^[7] Yield strength after aging gives a more precise measure of solute loss than the resistivity or hardness. However in the as-quenched condition, strength is not a reliable measure of solute loss.

In wrought products, the absolute value of yield strength includes an anisotropic component due to texture, that is, a tendency for crystallographic axes to take definite orientation relative to the strain axes of the material deformation. However when yield strength is measured in different directions for a variety of quench conditions from the same solutionized state, it is found that the loss of strength due

Fig. 14 Yield Strength versus solute, in W and T6 Tempers for a series of 7xxx alloys with Cu-Mg-Zn varied proportionately (J. T. Staley, courtesy of Alcoa)

to a poor quench is the same in the several directions. This indicates the quench affects the solute loss and hence the age-hardening, but not the texture-strengthening.

Vacancy Loss

Thermal fluctuations on the atomic scale create and annihilate lattice vacancies at incoherent surfaces such as grain boundaries and particle surfaces, as well as at individual dislocations. In thermal equilibrium, diffusion distributes the vacancies uniformly through the crystal lattice. The equilibrium vacancy concentration, C_v , varies with temperature as

$$C_v = C_0 \exp\left(\frac{-Q_v}{RT}\right) \quad (12)$$

Equation 12 is plotted in Fig. 15, using values of C_0 and Q_v reported as 1430 (at.%) and 64,670 J/mol, respectively.^[68]

As temperature is lowered during quench, the equilibrium vacancy concentration decreases according to Eq. 12. However, the actual vacancy concentration can be reduced only by diffusion to sites of annihilation. During a fast quench, vacancies are largely retained, so the vacancy concentration immediately after quench is greater than the equilibrium concentration.

Excess vacancies are essential to natural aging – the development of solute atomic clusters at room temperature. Firstly, diffusion of individual solute atoms in aluminum is by hopping into vacancies, so the movement of solute is directly proportional to vacancy concentration. Secondly, atomistic techniques such as positron annihilation lifetime spectroscopy (PALS) demonstrate the participation of vacancies in the initiation of clusters. The rate of atomic clustering is affected by temperature, by amount of solute, and by amount of vacancies. These factors are distinguished by the type of experiment shown in Fig. 16. Solutionized samples of alloy 7075 were quenched at various rates, with the solute loss being measured by increase of electrical conductivity. Then T6 yield strength was measured with various rates of heat-up for artificial aging. Clustering occurs only below a stability temperature (solvus), so the faster the heatup, the less time for cluster formation, the lower the number density of the η' hardening particles, and the lower the T6 strength.

Observations equivalent to those in Fig. 16 have been reported for other 7xxx alloys including 7108,^[17] 7050^[38] and 7055.^[34] The same effect is found in 6xxx alloys, but there the observations are complicated by the presence of

Fig. 15 Equilibrium vacancy concentration versus temperature, calculated from coefficients of Ref. [68]

Fig. 16 Yield Strength for Various Quenches and Four Rates of Heatup to Artificial Aging. Solute loss during quench indicated by electrical conductivity in %IACS (International Annealed Copper Standard). Arrows indicate that for quench producing W-temper EC of 41%IACS, the T6 yield strength is reduced 140 MPa by solute loss during quench, and a further 110 MPa when heatup at 55.6°C/h curtails cluster formation. Derived from Ref. [47] Courtesy of Alcoa

two types of clusters with distinct solvi. Only that with the higher solvus leads to β'' strengthening.

Commercial aging practices are designed to avoid penalties due to vacancy loss during quench. Thus for the 7075 alloy shown in Fig. 11, there is either a limit on heatup rate or a “first step” hold at temperature below the solvus of precursor to η' hardening particles. Hence, the metallurgical consequences of poor quench can be considered in terms only of solute loss.

Boundary Precipitates

Precipitates nucleated at grain boundaries differ in many ways from the others mention in “Precipitation Sites” section. Following are the main points:

Earliest nucleation. Grain-boundaries present the lowest barrier to nucleation. Hence these precipitates nucleate earlier than the same phase nucleated, say at a dispersoid, often by a factor of 3 in time or rate.

Growth and coarsening continue during aging. While nucleation of boundary precipitates is mostly during quench, a combination of fast quench and extended artificial aging may cause significant growth and coarsening during aging.

Nonlinear kinetics. The kinetics of growth and coarsening evolve somewhat differently for grain-boundary precipitates than for than for precipitates dispersed through the grain. Initial growth is faster than for the same nuclei dispersed, because of the high diffusivity along the grain boundary. Likewise, rapid coarsening begins once the

precipitates cover the boundary. However a slow growth continues indefinitely because in the large volume away from the boundary much solute remains unprecipitated or in fine particles.

Minor Effect on Strength. Although it is frequently possible in laboratory study to resolve the loss of strength specifically due to solute withdrawn to grain-boundary precipitates,^[49] for most alloys and practices it could as well be ignored. Detection of grain-boundary precipitation by hardness or resistivity seems unlikely.

Nonlinear Effect on Corrosion and Toughness. There are many instances where grain boundary precipitates are incriminated in problems with corrosion and/or toughness of high-solute alloys. However, property measures are not linearly related to precipitate development, as is the case with strength and dispersed precipitates. Even after decades of work in some cases, the relations of grain-boundary precipitates to properties are debated^[52,70]

Quantitative characterization of boundary precipitates is done for research into the kinetics and the relation to properties. Figure 17 shows some early data correlating fracture toughness to the fractional coverage of the boundary. A more recent example is Ref. [59].

TEM is limited for quantitative characterization of grain-boundary precipitates because of variation in foil thickness and in angle between grain boundary and foil surface. The only statistic reasonably collectible by TEM, other than PFZ thickness, is the distribution of precipitate diameters; an example is Table 4 of Ref. [20].

Fig. 17 Fracture toughness vs. area fraction of grain-boundary precipitates in two experimental alloys. Data source: Al-3%Li-0.5%Mn from Ref. [66]; Al-6%Zn-3%Mg from Ref. [65]

SEM (scanning electron microscope) with digital image analysis well suited to detailed characterization of grain boundary precipitates. The boundary is first traced manually by light pen. Then software is scripted to compute the total length of boundary, and the centers, area, and principal axes of all the boundary particles. Statistics are computed, then related to 3D by stereology.^[44] One significant statistic is the total particle area per length of boundary. Multiplying this by the fraction solute in the particle gives a surrogate for PFZ width, which is not well imaged in SEM.

TESTING QUENCH SENSITIVITY

Laboratory testing of quench sensitivity involves solutionizing multiple specimens of the material to be tested, applying several different controlled quenches, and one or more aging practices. Examination of the treated specimens can be any or all of

- metallography of quench precipitates, usually boundary precipitates
- one or more properties sensitive to solute loss (resistivity, hardness, strength)
- a property, usually corrosion or toughness, sensitive to boundary precipitates

This section briefly surveys the various procedures and representative results

Continuous Cooling

In this type of procedure, the rate of cooling during quench is supposed to be roughly constant over the range between solutionizing and aging temperatures (Fig. 4). A range of cooling rates is generated by a suite of quenching media: cold water, hot water, forced air, still air, etc. The specific experimental plan is supported by a calibrated chart relating the average cooling rate in the temperature range of interest to the quenching medium and the specimen thickness. Figure 18 is an example of such a chart used by L. A. Willey of Alcoa more than a half-century ago. Even if all the test specimens are the same thickness, the charted thickness information is useful to translate results from test specimens to full-size product, and also to design ballast attached to the test specimen only during quench, to achieve slower rates than otherwise possible.^[18]

In surveying experimental alloys for quench sensitivity, a common practice is to grade the candidates by the difference in yield strength at two selected cooling rates. Figure 19 is an example for an experimental Al-Mg-Si alloy. If property has been measured at three or more cooling rates, the data can be plotted to indicate a curve of property value extending from fast-quench towards slow-quench limits. Figure 20 is an example.

Data on property from multiple quench rates has also been collected using a Jominy end quench.^[37,42] This

Fig. 18 Cooling rate vs panel thickness for various cooling media (L. A. Willey, Courtesy of Alcoa)

Fig. 19 The difference between the yield strengths of fast-quenched and slowly cooled specimens used to measure the effect of various alloying additions on the quench sensitivity of an experimental Al-Mg-Si alloy

Fig. 20 The effect of average cooling calculated over the critical temperature range on mechanical properties used to quantify the quench sensitivity of aluminum alloys. The effect of various dispersoid-forming elements in Al-5.7%Zn-2.5%Mg-1.4%Cu alloy
Source: Holl^[27].

experimental technique provides cooling rate as a function of the distance from the quenched end, so that only one or several or several samples need by quenched. The compensating disadvantage is that only a small volume of material is available for each cooling rate. This limits observations essentially to Vickers hardness and possibly metallography. Tensile tests, toughness or corrosion tests would seem to be impractical for Jominy specimens.

A fundamental weakness in all continuous-cooling tests, is that they do not detect where in the temperature range any changes occur. Therefore, they are not suitable for “designing a quench” in which some purposeful change of cooling rate is made within the temperature range between solutionizing and aging. Furthermore, they

could be somewhat misleading when comparing materials which differ in the temperatures where metallurgical changes are happening during quench.

Interrupted Quench

Fink and Willey^[23] developed procedures using thermal paths termed “Interrupted Quench.” Specimens are transferred from the solutionizing furnace to a thermal bath at a predetermined temperature and held for a predetermined time before transfer to cold-water bath. This is repeated for a designed matrix of times and temperatures, including direct cold-water quench. Each sample is then aged and tested for tensile strength or other properties.

Fig. 21 TTP curves obtained by Fink and Willey for yield strength and tensile strength of 7075-T6

For each property, the results may be summarized as TTP (Time-Temperature-Property) diagrams. Figure 21 is the TTP diagram first shown for by Fink and Willey for alloy 7075-T6. The lines are contours representing the loci of times at temperatures required to precipitate solute that reduced the property (yield strength or ultimate strength) realized after aging, to a certain percent relative to that of rapidly quenched material.

In the decades following, such diagrams were constructed in the Alcoa Laboratories for other aluminum alloys. In Russia, extensive similar work was done for most Russian alloys (Davydov, 1973). In many cases, the suite of hold temperatures was extended down into the age-hardening range (see Fig. 4), so the test gave information about aging response as well as about quench response. Particularly in academic institutions, hardness and/or resistivity were used as a less expensive procedure giving essentially the same information, albeit usually with less precision.

It was not immediately obvious how best to use the information being compiled. The major breakthrough came with the work of Ref. [22]. They developed a numerical procedure by which the information in a TTP diagram could be used to predict the property for an arbitrary quench path. That opened possibilities for diagnosis and design of process: Investigating in simulation if a certain problem could have been caused a certain way, or if a certain process change was worthwhile. The Evancho-Staley method is reviewed and extended in the following “Numerical Models” section.

Figure 22 is an example of a TTP diagram for two properties. This work was done on 7050-W, which is not a product, to investigate some fundamentals. As-quenched resistivity was reduced to define contours of 90% and 80% solute retained. Comparing these contours with those on Fig. 21, both have the same general “C-curve” shape, but those for 7050 are at slightly longer times. This is consistent with the result that the Al_3Zr dispersoids in 7050 precipitate less solute than the $Al_{18}Mg_3Cr_2$ dispersoids in 7075, as already suggested by Fig. 20. The other property shown in Fig. 22 is corrosion mode. The dominance of IG (intergranular corrosion) inside the circle is presumed due to an anodic, Cu-depleted zone caused by grain-boundary precipitation. The time to develop these corrosive conditions at the grain-boundary is very short, less than the time for solute loss detectable with resistivity, which has been known for a long time. Figure 22 also indicates that the corrosion mode changes from IG back to pitting if the hold near 350°C is continued long enough for significant solute loss to dispersoids. The conventional explanation is that solute removal in the matrix reduces galvanic difference between matrix and PFZ, which reduced the driving force for IG corrosion.

Figure 23 is another example of a TTP diagram for two properties, with a pattern similar to that shown in Fig. 22. This time solute loss is measured by yield strength, the

Fig. 22 TTP for corrosion and resistivity in 7050-W (Byrne, 1996; Staley et al.^[57])

Fig. 23 TTP for Toughness and yield strength, 7085-T6

effect of grain boundary precipitate is measured by toughness. For quench interrupted 300°C–350°C, only a short time is needed for precipitates to weaken the grain-boundary enough for toughness to drop nearly in half. At longer hold times, when solute depletion becomes significant, the matrix becomes more ductile, and the toughness actually increases. A survey of all available TTP diagrams for toughness^[51] found this pattern to be general.

Most TTP diagrams for toughness have used the Kahn tear test.^[29] This was originally developed to deal with the ductile-brittle transition in steels, then standardized as ASTM B871 for aluminum sheet.^[30,31] Later the theoretical work in fracture mechanics led to the stress-intensity factor **K** and the ASTM standards E399 and E561 for measurement of **K_{IC}** and **K_R** respectively, which are the procedures used today in specifying toughness of aluminum products. The Kahn tear test produces two numbers, the Unit Initiation Energy (UIE), and Unit Propagation Energy (UPE). These loosely correlate to each other and to the square of stress-intensity factor **K**. Theoretical and experiment search for a useable general relation between **K** and the Kahn test has come up empty. Any laboratory procedure for IQ on a Kahn specimen, could also be used for a CT (Compact Tension) specimen to be tested by ASTM E561. The mechanical test machine can also be used to apply stretch between quench and age. This procedure for toughness testing after IQ is to be preferred because ASTM E561 includes much more sophisticated validity checks than ASTM B871, and the results can be better related to full-scale toughness tests. The E561 procedure was used in the work for Fig. 23, as well as by Ref. [55].

A pattern of interrupted quenches is also used with only metallography done on the specimens. Sometimes results can be expressed as “fraction transformed,” as for TTT diagrams in steel. Usually in aluminum, it is more feasible to identify the first appearance of a new phase. Figure 24 is an example of this type of diagram. Some other published examples are:

2024 (Ives et al.^[28])
 Al-Mg-Si (Fister and Pryor^[24])
 6013 (Davydov et al.^[15])
 6351 (Eskin et al.^[21])
 6061 (Massardier et al.^[39])
 7010 (Godard et al.^[25])
 USSR Alloy 1420 (Davydov et al.^[16])
 2090 (Staley^[55])

There is no standard terminology for this type of diagram. Some authors call them TTT or TTP diagram, but those terms are already in use for other purposes. (Ives et al 2020) used the term “nucleation diagram.” In this vein, we refer to them as TTN (Time-Temperature-Nucleation) diagrams.

Delayed Quench

Fink and Willey^[23] also introduced a “delayed quench,” in which a specimen is cooled in still air until a target temperature is reached, then is quenched in cold water. We have found this a worthwhile adjunct to either of the laboratory test paths described above. Operationally, it is only slightly more complex than continuous cooling, and

Fig. 24 Time-Temperature-Nucleation curves for alloy 6013
Source: Davydov et al. 1998.

easier than interrupted quench. As an adjunct to completely continuous cooling, it can provide information about the temperature of metallurgical change, which is otherwise lacking. As an adjunct to interrupted quench, it provides some check on the model-based procedures, discussed below, used to predict the response to continuous cooling from measurements after interrupted quench. Figure 25 gives an example of results from Delayed Quench on toughness specimens. It shows a pattern like that in Fig. 23: toughness being drastically reduced by grain-boundary precipitates, then increasing somewhat as solute loss becomes significant.

NUMERICAL MODELS

Evancho-Staley Process-Property Model

Development of the Evancho-Staley model was stimulated by installation at Alcoa's Davenport Works of equipment for continuous heat-treatment (solutionize and quench) of wide sheet products. The most quench-sensitive of the products to be moved onto this equipment was 2024-T4 sheet, known to be prone to intergranular (IG) corrosion if not rapidly quenched. Previously (Willey, 1943) had performed Interrupted-Quench tests on 2024 and produced a "C-curve" showing $t_c(T)$, a "critical time" as a function of temperature. This curve separated the specimens of short hold time, generally free of IG, from the specimens at long hold time, generally exhibiting IG. In relating these old test results to the current equipment start-up, Staley,^[53] recognized and solved two problems.

The first problem was how to use the IQ data to predict whether or not IQ would be a problem for a given product

thickness, speed and spray settings. This was solved by defining a "Quench Factor", QF:

$$QF = \sum \frac{\Delta t}{t_c(T)} \quad (13)$$

The actual cooling path was to be approximated by a succession of short isothermal segments, then summing over these segments the hold time relative to critical time. The prediction was that continuous-cooling with $QF < 1$ would not lead to IG corrosion, continuous-cooling with $QF > 1$ would lead to IG corrosion.

The second problem recognized and solved in Ref. [53] was that the C-curve in (Willey, 1943) was drawn on nominal hold times, and did not correctly account for the path from solutionizing temperature to hold temperature. The answer was to redraw the curve to make it "self-consistent," that is, the Quench Factor calculated with Eq. 13 and the actual laboratory cooling curves would correctly segregate the IQ corrosion test results. Since the cooling curves from (Willey, 1943) could not be satisfactorily retrieved, fresh experiments were conducted by (Vruggink, 1969), which resulted in a corrected curve of critical time "C-curve" $t_c(T)$, and a validation of the Quench Factor method for this situation.

This applied work was followed by the collaboration reported as Ref. [22,54]. First, it was recognized that the Quench Factor method was essentially equivalent to that proposed in Ref. [9] for using isothermal data to predict transformations during continuous cooling. Next, it was recognized that the connection to CNT (Classical Nucleation Theory) made in Ref. [8] could be mined for an analytic expression of critical time $t_c(T)$, replacing the graphical definition used initially. Then a computer

Fig. 25 Toughness and Strength Data from Delayed Quench (DQ) Tests on Alloy 7085. Note slow rate of cooling, 625 seconds to 250C, dues to the thickness of the toughness specimen. Toughness measured as KR at 25% secant, valid per ASTM E561 (R. T. Shuey, courtesy of Alcoa)

program could be written to adjust the coefficients in the analytic model, to minimize difference between the laboratory test results and the predictions from integration over the actual cooling paths in the IQ tests. Finally, the whole technology could be applied to predict strength after continuous cooling from the IQ results reported by Ref. [23].

The analytic expression for critical time proposed by Evancho and Staley^[22] is

$$t_c = K_2 \exp \left[\frac{1}{RT} \left(\frac{K_3 K_4^2}{(K_4 - T)^2} + K_5 \right) \right] \quad (14)$$

This matches the reciprocal of nucleation rate given in Eq. 6, with the correspondences

$$K_3 = \frac{1}{2} N_A K_N^3 \left(\frac{V_M}{\Delta H} \right)^2 \quad (15)$$

$$K_4 = T_s \quad (16)$$

$$K_5 = Q_D \quad (17)$$

where N_A is Avogadro's Number, 6.022×10^{23} , used here to convert the Boltzmann constant "k" to gas constant "R", and T_s is the lesser of the solvus and solution treatment temperatures. A similar exact match is not possible for the overall prefactor K_2 , because the critical time in the Evancho-Staley model represents the cumulative effect of nucleation and growth. Representative values for Q_D are provided in Table 4. T_s values for quench precipitates observed in several commercial aluminum alloys are listed in Table 9. Thus for K_4 and K_5 , good

numerical values can be obtained from independent thermodynamic data.

Equation 14 supposes the temperature dependence of the combined process is the same as the temperature dependence of nucleation. This can be supported by theoretical analysis of the combined process. Comparison to Eq. 14 with theory of phase transformations does establish that K_2 is inversely proportional to the nucleation site density N_s . This result is useful for interpreting empirical values of K_2 found in fitting the Evancho-Staley model to data. The expected relationship between K_2 and K_3 for different nucleation sites is shown schematically in Fig. 26. However, there is currently no good alternative to fitting data on quench sensitivity.

A plot of Eq. 14 with coefficient determined for 2024-T851^[28] is provided in Fig. 27. Traditionally t_c is plotted in the x-axis and T is plotted in the y-axis. The effect of each coefficient on the nose of the C-curve is presented schematically in Fig. 28. Coefficients K_2 and K_5 shift the location of the nose in time whereas K_3 and K_4 affect both the time and temperature of the nose.

In the process-property model of Evancho and Staley, the change in the attainable property, σ , during the quench, follows:

$$\frac{d\sigma}{dt} = - \frac{\sigma - \sigma_{\min}}{t_c} \quad (18)$$

with the boundary condition that $\sigma = \sigma_{\max}$ at $t = 0$. The term $\sigma_{\max}$ is the property attainable after a quench at an infinite rate, i.e., with no quench precipitates, and $\sigma_{\min}(T)$ is the strength remaining at limit of precipitate growth. For an infinitely fast quench, interrupted at a temperature T for a time t , the result of integration is

$$\sigma = \sigma_{\min}(T) + [\sigma_{\max} - \sigma_{\min}(T)] \exp \left(- \frac{t}{t_c} \right) \quad (19)$$

Table 9 Chemical composition of several commercial aluminum alloys and the quench precipitates for each one listed along with solvus temperature, maximum volume fraction and enthalpy of precipitation

*: Solidus temperature. Solvus temperature for available solute is higher than the solidus.

which is plotted in Fig. 28. Thus for an ideal isothermal hold, $t_c(T)$ is the time-constant for nucleation and growth of quench precipitates.

The incremental property loss $\Delta\sigma_j$ in the time interval Δt is found by:

$$\Delta\sigma_j = (\sigma_{j-1} - \sigma_{\min}(T)) \cdot \left(1 - \exp\left(-\frac{\Delta t_j}{t_c}\right) \right) \quad (20)$$

Finally, property attainable at the end of quench is then calculated by

$$\sigma = \sigma_{\max} - \sum_{j=1}^n \Delta\sigma_j \quad (21)$$

Evancho and Staley recognized that $\sigma_{\min}(T)$ “increases considerably with increasing temperature as the solvus temperature is approached”.^[54] However, the equations actually used during the following three decades, did not express this understanding. These equations include:

- $\sigma_{\min} = 0$ [Evancho and Staley^[22]]
- $\sigma_{\min}$ best-fitting constant [Swartzendruber et al.^[48]]
- $\sigma_{\min} = b_0 + b_1T + b_2T^2$, with best-fitting coefficients b_0 , b_1 , b_2 [Staley et al., 1993]

The process-property model of Evancho and Staley outlined above has been applied successfully to almost all heat-treatable aluminum alloys to predict properties, such as yield strength, ultimate tensile strength, hardness, electrical resistivity. Despite this success, it was determined that quench experiments need to be conducted again to

determine new coefficients when there are changes in the chemical composition, microstructure, alloy temper and/or property of interest. For instance, different sets of coefficients for properties such as ultimate tensile strength, yield strength, hardness, electrical resistivity were reported for 2219^[48] and 2024^[28] despite the same microstructure governing each property.

Process-Structure-Property Model

It is of course possible to calculate the evolution of volume fraction of quench precipitate(s), f , during the quench. Precipitate volume fraction is also linearly related to solute. That is because for each element, the amount in solution plus the amount precipitated equals the total in the alloy.

**Fig. 26** Relative values of K_2 and K_3 for different nucleation sites (Schematic)

Fig. 27 Plot of Eq. 14 with the coefficients reported for 2024-T851^[28]

Fig. 28 Effects of each coefficient on critical time $t_c(T)$

Hence, we may suppose strength depends linearly on volume fraction f , as follows:

$$\sigma = \sigma_{\max} - K_p \cdot f \quad (22)$$

In isothermally interrupted quench, the limiting strength $\sigma_{\min}(T)$ is likewise related to limiting precipitate amount $f_{\text{eq}}(T)$:

$$\sigma_{\min}(T) = \sigma_{\max} - K_p \cdot f_{\text{eq}}(T) \quad (23)$$

The equilibrium volume fraction, f_{eq} , is written as

$$f_{\text{eq}}(T) = f_{\max} \left[1 - \exp \left(\frac{Q_s}{R} \left(\frac{1}{T_0} - \frac{1}{T} \right) \right) \right]; T \leq T_s \quad (24)$$

$$f_{\text{eq}}(T) = 0; T \geq T_s$$

where Q_s is the enthalpy of precipitation and $f_{\max}$ is the volume fraction precipitate which completely exhausts the available solute. Values for Q_s and $f_{\max}$ for quench precipitates observed in several commercial aluminum alloys are listed in Table 9. Substituting Eqs. 22 and 23 into Eq. 18 gives:

$$\frac{df}{dt} = \frac{f_{\text{eq}} - f}{t_c} \quad (25)$$

This can be integrated over the quench path $T(t)$ with the initial condition $f = 0$, as an alternative to integrating Eq. 18 with initial condition $\sigma = \sigma_{\max}$. The finite-difference corresponding to Eq. 20 is:

$$\Delta f_j = (f_{\text{eq}} - f_{j-1}) \cdot \left(1 - \exp \left(\frac{-\Delta t_j}{t_c} \right) \right) \quad (26)$$

Fig. 29 Strength loss for interrupted quench

The integral for an ideal interrupted quench is

$$f = f_{eq} \left(1 - \exp \left(-\frac{t}{t_c} \right) \right) \quad (27)$$

After integration, Equation 22 is applied to predict strength. Figure 30 illustrates how particular values of strength correspond to particular values of precipitate volume fraction.

When one type of quench precipitate is assumed, the process-structure-property model yields identical results to the original Evancho-Staley model.

Data Fitting

Data collected from quench experiments following interrupted and/or delayed quench, are used along with the entire cooling curve for every specimen to determine coefficients K_2 - K_5 , σ_{max} and any coefficient for σ_{min} . Using nominal holding times for interrupted quench experiments is not sufficient because cooling to and from the hold temperature is important, especially in alloy with high quench sensitivity, such as 7075-T6. By taking the entire cooling curve into account, Evancho and Staley^[22] modified the TTP curves of Fink and Willey, who used nominal hold times. The actual noses of curves were at much shorter times than originally calculated by Fink and Willey.

The coefficients of Eq. 14 have been traditionally determined by varying them along with σ_{max} and any coefficient(s) for σ_{min} until the sum of squares for error (SS_E) is minimized. This approach, however, (i) often yield implausible values for K_4 and K_5 , although these coefficients

Fig. 30 Postulated linear relation between strength and precipitate

should be driven by the thermodynamics of the alloy, (ii) results in the overparameterization of the problem, which consequently introduces local minima having significantly larger errors than the true solution.^[50] This was first noticed by Swartzendruber et al. (1980) in their study on 2219. The authors noticed that the same SS_E was obtained for various values of K_5 , indicating the presence of too many adjustable coefficients in the model. Consequently^[28] in their study on 2024, used the activation energy for the diffusion of Cu for K_5 , noting that Cu is the element found in the quench precipitates of 2024 that diffuses most slowly.

Nevertheless, it is true that SS_E can be lowered considerably if all coefficients are allowed to vary in most cases.^[61] This is an indication of the presence of multiple C-curves for multiple quench precipitates (different location and/or

stoichiometry), as is the case in all commercial aluminum alloys investigated by the authors. A K_4 value larger than the T_s values listed in Table 9 indicates the presence of an upper C-curve (precipitation on grain boundaries). A K_5 lower than the Q_D values listed in Table 4 indicates the presence of a lower C-curve, usually associated with a different phase nucleating at a lower temperature than the main quench precipitate.

Multiple C-Curves

The formulation suggested initially by Evancho and Staley provides good results for dispersed particles with respect to both time and temperature. For grain boundary precipitates, however, the time dependence is not exponential. After nucleation, there is an initial rapid growth due to ease for solute atoms to diffuse along the grain boundaries. This rapid growth cannot be modeled by QFA. After the PFZ is developed, there is a very long stage during which the growth rate is slow as the PFZ evolves to a low gradient extending further out into the grain. This slow expansion of PFZ can be ignored for quenching but is dominant in billet cooling.

All QFA equations consider only a single type of precipitate, while nearly all Time-Temperature-Nucleation plots and metallurgical investigations show multiple types of precipitates, as discussed previously. In this section, the QFA model is expanded to account for multiple precipitates. The improved model establishes process-structure-property relationships by accommodating multiple quench precipitates.

The amount of each quench precipitate is represented by a unitless microstructural state variable S . For arbitrarily long isothermal hold, in the absence of competing precipitates, the limiting value, S_{eq} , is

$$S_{eq}(T) = 1 - \exp\left[\frac{Q_s}{R}\left(\frac{1}{K_4} - \frac{1}{T}\right)\right]; T \leq K_4 \quad (28)$$

where K_4 is now taken as the solvus temperature for each population of quench precipitates (Table 9). S_{eq} represents the equilibrium amount of S at a given temperature. The evolution of quench precipitates is modeled by

$$\frac{dS}{dt} = \frac{S_{eq} - S}{t_c} \quad (29)$$

K_5 in Eq. 29 is now taken as the stoichiometrically-averaged activation energy (Q_D) for diffusion (J/mol) listed in Table 4. This approach avoids the older approximation of considering just the slowest-diffusing element as used by Ives et al. for 2024, which is now recognized as usually not very accurate.^[64]

The numerical algorithm for each quench precipitate is:

$$\Delta S_i = (S_{eq} - S_{i-1}) \left[1 - \exp\left(\frac{-\Delta t_i}{t_c}\right) \right] \quad (30)$$

At the end of the quench, S is found by:

$$S = \sum_i \Delta S_i \quad (31)$$

Strength can then be estimated by

$$\sigma = \sigma_{max} - \sum_j k_j S_j \quad (32)$$

where j is for the quench precipitates modeled and k_j is the strength coefficient (MPa). The following constraint is enforced:

$$\sigma_{int} = \sigma_{max} - \sum_j k_j \quad (33)$$

The values for σ_{int} varies usually between 50 and 150 MPa. Although Eq. 33 lacks a physical meaning, it is a useful constraint in many cases to avoid erroneous extrapolation to long times to make up for incorrect assumptions in (i) the competition for the remaining solute between adjacent C-curves, and (ii) the growth rate of quench precipitates on grain boundaries. This constraint needs to be relaxed in cases where a PFZ is formed within the matrix, such as around dispersoids in 6XXX alloys.

This model has been applied to D357-T6 alloy. The C-curves for the precipitation of β on eutectic Si particles and in the matrix, as well as for the loss of Si to eutectic Si are shown in Fig. 31.^[62] The iso- σ_y curves are presented in Fig. 32. This model with multiple C-curves have been successfully applied to all datasets, both in the literature and proprietary.

TECHNOLOGY STATUS

Recommendations on Use of Existing Technology

Following are some procedural lessons about quantitative characterization of quench sensitivity in aluminum alloys:

- Use actual recorded temperature paths for fitting property data; TTP plots of raw property data are only for quality control.
- Make a DQ series as a supplement to any IQ test suite.
- Fix the coefficients K_4 (T_s), $K_5(Q_D)$ and Q_s from thermodynamics.
- For data with multiple good measures of solute loss, fit properties jointly rather than independently.
- Check phases precipitated, and precipitation sites, by selective metallography. Then make a multi-C fit when indicated.
- Use Jominey results only for CCP charts, not predictions for arbitrary quench path.

Thoughts for Future Development

Interconversion of Solute Loss Measures. It has been established that yield strength, (Vickers) hardness, and W-temper resistivity all are linear measure of the same “solute loss.” Yet lacking are validated guidelines for converting work done with one such test to predictions about another such test.

Interpolation of Solute Loss with Composition and Processing. The Evancho-Staley method as applied so far, considers each alloy, and each fabrication sequence, as an independent case. Yet understandable difference are found whenever the method is applied to multiple alloy compositions, homogenization temperatures, and/or amounts of

work. Honoring the physical meaning of the coefficients (Eqs. 15 through 17), it should be possible to interpolate models continuously with composition and processing.

New Equations for Boundary-Controlled Properties. The Evancho-Staley model, with modest amendments outlined above, seems to have no substantial flaws for properties defined by solute loss. Some new equations are needed to model the fundamentally nonlinear behavior indicated in Fig. 22 for IG corrosion, and in Fig. 23 for toughness.

Quench-Aging. The Evancho-Staley formalism supposes separate quenching and aging steps. Methods comparable to the Evancho-Staley formalism have been developed for control of artificial aging.^[5] Potentially these

two lines of work could be combined into a formalism for control of quench-aging. Models for boundary-controlled properties – toughness and intergranular corrosion – ultimately will need combined modeling of quenching and aging.

Microgravity Crystallization for High-Tech Castings

Hans M. Tensi

Technical University of Munich, Munich, Germany

Abstract

In this article, an overview of the development of microgravity crystallization of aluminum castings will be provided. Topics to be discussed include: industrial process development, microgravity experiments performed in space, and development of high-strength castings in microgravity environments.

Keywords: Crystallization parameters; Dendrite coarsening; High-strength castings; Microgravity; Quenching.

INTRODUCTION

More than 350 years ago an artist illustrated the desire of mankind to explore the universe through space exploration (Fig. 1).^[1] This required the scientist to leave the world with which he was familiar to learn many new and unimaginable, miraculous and possibly even frightening things but which would also provide the potential to impart wisdom and a better understanding of the intimate world.

This was the situation, when man first started travelling into space in 1961. In the beginning the primary emphasis was to develop technology to take the cosmonauts and the astronauts into space and bring them back to earth safely. However, even during these early stages of space exploration, scientists began to demand the opportunity to conduct experiments to obtain a new or better understanding of physical, chemical and biological events occurring under the microgravity conditions of space. The objective of this work was to obtain sufficient knowledge to control fundamental properties in such a way to permit the development of new processes and/or “new materials.” Of course, nobody really expected this work to lead to the addition of new elements to the Periodic Table.

For example, an important objective of material science in space is the investigation of the influence of space-conditions on the crystallization of metallic microstructures. Although castings have been used since pre-historic times, the knowledge of how to influence these microstructures and their correlation with mechanical properties is not well understood even today.^[2] Improvements of the quality of AlSi-castings could not have been realized without the fundamental knowledge gained by so-called mg-experiments or only with a much greater number of empirical experiments under the much greater gravity conditions present on earth.

Experiments in the space are called μ /g-experiments, because the “1 g” acceleration on earth is not exactly reduced to zero while orbiting the earth over a distance of about 300 km; a residual acceleration of about 10^{-3} to $10^{-4} \times “1 \text{ g}”$ is caused by atmosphere friction and movements of the space shuttle while being maneuvered.

One of the first applications of μ g-experiments was to develop safety castings for aerospace applications and microgravity conditions. This led to the subsequent development of the first commercial car to be constructed completely from aluminum, the “AUDI A8” shown in Fig. 2. In this chapter, the development of μ g-crystallization of aluminum alloy castings will be discussed.

APPLICATION OF FUNDAMENTAL SCIENTIFIC KNOWLEDGE FOR INDUSTRIAL PROCESS DEVELOPMENT

The influence of crystallization conditions and alloying elements on casting morphology are not known because the mechanisms of formation casting morphologies is largely unknown. Quality improvement of castings requires a detailed answer to the following questions:

1. Which crystallization parameters and which chemical additions to the casting alloy composition influence on the mechanical properties?
2. Can the influence of these parameters on mechanical properties be quantified?
3. Is there an additional effect of these parameters on the mechanical attributes, and very importantly, what limitations must be considered for the different parameters?

Fig. 1 “The Doubter”, wood-block printing from an unknown artist 1520–1530^[1]

Fig. 2 AUDI A8; the pressure die castings in the “space frame” structure of this car have to meet extreme qualitative safety demands (Courtesy of AUDI AG, Ingolstadt, Germany)

One illustration of this is the mass transport during crystallization. Figure 3 visualizes this problem with the development of high-strength castings. However, this problem only be resolved with the use of μg -experiments to determine how mass transport in the melt in the vicinity of the solidification front is influenced by diffusion and by convection. For this work, the kinetics of the crystallization process must be explored by comparison of 1 g-experiments and μg -experiments, under identical crystallization parameters such as velocity of the solidification front and the temperature gradient preceding it. In space, convection caused by gravity is eliminated; only the so-called microconvection in the vicinity of the solidification front and the effect of diffusion are active for the mass transport. Under 1 g conditions, the influence of diffusion on the crystallization effects is superimposed by the influence of different kinds of convective mass transport.

Returning to the question of the specific material structure parameter influence on the mechanical properties: Many metallographic structures exist in the cast material which are visible with an optical microscope (OM). Sub-microscopic structures are only visible under conditions of very high magnifications (over 10^3) and using specially

prepared probes. This research can be performed using electron microscopes such as transmission (TEM) and scanning electronic microscopes (SEM). Quantitative determination of these structures must be carefully carried out and is to be related with the most important mechanical values like ultimate strength (R_m), yield strength (R_p) and the fracture strain (A_g). With the knowledge of the influence of crystallization parameters on material structures and their corresponding influence on mechanical strength, mechanical behavior at different positions in a cast part can be defined from the local different crystallization parameters in addition to localized different material structures! This is illustrated schematically in Fig. 4.

An important additional effect is provided by the type of macroscopic solidification occurring within the part. It is important to distinguish between the conventional solidification (so-called unidirectional crystallization) and the normal solidification (unidirectional solidification). Figure 5A,B illustrates the OM structures of an un- and unidirectional solidified AlSi-alloy with 7 wt% Silicon, exhibiting nearly the same physical solidification parameters (local solidification time $t_L = 333$ sec for unidirectionally (A) and $t_L = 280$ sec for unidirectionally (B)

Fig. 3 Present situation in developing high strength castings in the technical and scientific line

Fig. 4 Local different interaction of crystallization, microstructure and mechanical properties having a defined alloy composition (schematic)

crystallized AlSi). The different macroscopic crystallization processes are also shown: For unidirectional solidification, only one solidification front runs through the melt; for unidirectional solidification, a number of nuclei are created

Fig. 5 Metallographic structures of an unidirectionally (a) and unidirectionally (b) crystallized AlSi 7-alloy with the local solidification times $t_f = 333$ sec (a) and 280 sec (b); the schematic figures show the different geometry and growth direction of the solidification fronts^[2]

Fig. 6 Wall of a shrink hole with dendrites in cast AlSi-alloy (SEM picture; ca. 1500×)

from which the solidification fronts are moving through the melt toward each other. Of course, if the morphology of the metallographic structures influences the mechanical behavior of cast materials, the straightening of structures will also influence it! The main influence by the type of macroscopic solidification is provided on the “endurance fatigue life.” Further, the unavoidable presence of “micro shrink holes” in the conventional cast parts exhibits a disadvantageous effect on mechanical properties. Figure 6 is an SEM picture of a shrink hole in cast AlSi 7 alloy; this “micro shrink hole” illustrates the sharp notches, which increase the localized mechanical stresses.

To characterize the crystallization parameters, having an unidirectional solidifying melt, the velocity V_{SF} [m/sec] of the solidification front (SF) and the temperature

gradient G_{SF} [K/sec] in the melt in front of the SF must be precisely measured. The magnitude of these two parameters on the crystallized metallographic structures is illustrated by three examples in Fig. 7. One condition is with special crystallization parameters, low values of V_{SF} and high values of G_{SF} , where only one solidification front with a solidified volume consisting of one phase. A so-called single crystal (Fig. 7A) is obtained. Increasing V_{SF} and/or decreasing G_{SF} produces a cellular structure of the solidification front and the crystallized volume changes to a cellular morphology as shown in Fig. (B). Further increasing V_{SF} produces a dendritic solidification front and the mostly existing dendritic structures with eutectics in technical cast volumes is observed as illustrated in Fig. 7C. Additional experiments to be described

Fig. 7 Metallographic longitudinal microsections of three unidirectionally solidified probes of the same AlCu0.3 alloy. In each case: above quenched liquid, below unidirectionally solidified volume under 1 g conditions;^[3] (a) smooth SF: $V_{SF} = 0.51$ mm/min; $G_{SF} = 11.2$ K/mm ($M = 73:1$); (b) cellular SF: $V_{SF} = 0.73$ mm/min; $G_{SF} = 9.2$ K/mm ($M = 37:1$); (c) dendritic SF: $V_{SF} = 2.2$ mm/min; $G_{SF} = 6.4$ K/mm ($M = 76:1$)

subsequently, were performed under μg -conditions in the space with the pure alloy AlCu 0.3 (0.3 wt% Copper) to determine the effect of mass transport in the melt in the vicinity of the solidification front; see Fig. 3? Of course, these solidification parameters cannot be defined during an unidirectional solidification! Therefore the so-called “local solidification time” t_l [sec] is measured. During the time t_l the temperature drops down from the liquidus temperature T_L [°C] of the alloy up to their eutectical temperature T_E [°C]. Between these temperature limits, the solidification of the melt runs out completely with the (linearized) cooling velocity T [K/sec]. The t_l time can be measured easily by a so-called thermo-analysis. To compare the crystallized volumes of un- and unidirectionally solidified cast materials with their different crystallization parameters, the following relations are helpful:

$$t_l = \frac{(T_L - T_E)}{T} \quad (1)$$

$$T = G_{EF} \times v_{SF} \quad (2)$$

and from (1) and (2) using the fact that $(T_L - T_E)$ is constant for a defined alloy follows:

$$t_l = \text{const}(G_{EF} \times v_{SF})^{-1}$$

Figures 8 and 9 illustrates examples of the morphology of the so-called dendrites and the eutectic volume between them. The dendrites crystallize first from the melt and consist mainly from α -Aluminum-phases with a very low content of alloying elements. Their geometry is given by the crystallographic structure (face centered cubic-ffc) and their morphology by the crystallization parameters. Figure 8 illustrates the (primary) dendrite spacing “e” and the (secondary) dendrite arm spacing “ d_s ”. Of course, the determination of “e” is only possible having unidirectional solidified cast materials. As will be shown later, “e” and “ d_s ” are influenced by the solidification parameters and by the μg -conditions.

Experimental and theoretical research has shown that there exists a strong influence of the crystallization velocity T on the values “e” and “ d_s ” which are determined from Eqs. 3 and 4:

$$e = \text{const} \times T^{-0.5} \quad (3)$$

where $T = dT/dt$ [K/sec] in the temperature region between start and end of solidification

V_{sf} = velocity of the solidification front [m/sec]

G_{sf} = temperature gradient in front of the solidification front [K/mm]

and

$$d_s = B \times (M \times t_l)^{0.3...0.4} \quad (4)$$

Fig. 8 Schematic view of the dendritic structural characteristics in the stage of unidirectional solidification

Fig. 9 Schematic view of the interdendritic eutectic structural characteristics

where t_l = local coarsening time [sec]; this is the time during which the dendrites are surrounded by liquid phases. The coarsening proceeds by minimizing the total energy

B = a constant geometric factor 4.36 ... 5.5

M = a material factor to be calculated from the physical and metallurgical values of the melt:

$$M = \frac{\left\{ 2 \times \sigma \times D_L \ln \left(\frac{c_E}{c_0} \right) \right\}}{\left\{ \Delta H \times (1 - K_0) \times m_L \times (c_E - c_0) \right\}};$$

where σ = surface tension [N/m]
 D_L = diffusion coefficient [cm²/sec]
 c_E and c_0 = alloying concentration (here silicon) at the eutectic point and the initial concentration
 ΔH = heat of fusion
 K_0 = distribution coefficient
 m_L = gradient of the liquidus line

Using these equation, M calculated for AlSi 7 is 16.3×10^{-12} [cm³/sec].

The evaluation of the eutectic morphologies are shown in Fig. 9. The details of the eutectic (having different magnifications) explain the evaluated morphology values like “Silicon content of eutectic”, “volume fraction of eutectic”, “degree of refining ϵ ”, “median section a_{Si} ” and “shape factor F_{shape} ” of cut Silicon phases and the “average eutectic spacing λ ”. Because the “average eutectic spacing λ ” (the free path of the so-called dislocations in the α -Al-phases) has a dominant influence on the mechanical values, only λ will be used here. Influence of the cooling rate T ($= V_{SF} \times G_{SF}$) on the λ -values is given in Eq. 5.

$$\lambda = \text{const} \times (V_{SF} \times G_{SF})^{-n} \quad (5)$$

where $n = 0.5$ for AlSi 7 (measured values for n from 0.44 to 0.62 for technical AlSi-alloys with Silicon contents in the range between 5 and 11 wt%)

The magnitude of the influence of these microscopic structures by the solidification parameters is illustrated in Fig. 10 where the dependance of “ e ” and “ d_s ”, of T for six alloys based on the basic (pure) AlSi 7, beginning with “A357” and with 5 modification of additional alloying elements. In the area of lower T -values (between 40 to about 300 [K/sec]), where the influence is strong, alloying elements exhibit no effect. An additional comparison is provided by two pure binary AlSi alloys (AlSi 7 and AlSi 11) and the corresponding pure ternary alloys with different additions with Magnesia and Antimony. Figure 11 show the comparable diagrams where the influence of the distance from the eutectic Silicon concentration is clear!

Although there is no influence of alloying elements on dendrite morphology, the effect of alloying elements and cooling rate T on the eutecticum morphology is given in Fig. 12 for 1.0 wt% Copper added to a A357 alloy and for AlSi7Mg (corresponding to A357). Micrographs of the eutectic areas for different T -values (or put into words other for different wall thicknesses of the casting) show the change of the geometric structures of the Silicon phases. For example the change of the median section of a_{Si} is evaluated here. By the addition of copper to A357 in the area

Fig. 10 Influence of cooling rate $T = G \times v$ on the primary and secondary dendrite spacings for 6 technical alloys with constant Si-contents

of low T -values (or high wall thickness), the a_{Si} -values are higher in the range of $40 < T < 200$ [K/min].

The isolated influence of the microstructures “ d_s ” and “ λ ” on the mechanical value R_m is exemplarily illustrated in Fig. 13. In both cases, the tensile strength increases with decreasing “ d_s ” and decreasing “ λ ”. The following half-empirical relation between the mechanical value R_m and the morphology values d_s and λ was found for hypoeutectic AlSi alloys:

$$R_m(C_0, d_s, \lambda) = K_{conc.}(C_0) + K_{Dendr.}(C_0) \times d_s^{-0.5} + K_{Eut.} \times \lambda^{-0.5} \quad (6)$$

where R_m = tensile strength (calculated); C_0 = Si-concentration; d_s = dendrite arm spacing (secondary dendrite arm spacing); λ = eutectic spacing of Si-phases; $K_{conc.}$ = a constant, depending on Si-concentration (for $7 \text{ wt}\% < C_0 < 11 \text{ wt}\%$ $K_{conc.} = 65$); $K_{Dendr.}$ = a constant, depending on Si-concentration (for $7 \text{ wt}\% < C_0 < 11 \text{ wt}\%$ $K_{Dendr.} = 500$); $K_{eut.} = 115$.

Of course the relationship between the OM-morphology and the mechanical values works correctly only without the effect of age-hardening of the α -Al-phases (the α -phases of the dendrite volume and in the eutectic mixture). This means that pure AlSi-alloys with 7 and 11 wt% Silicon contents and the corresponding AlSi alloys with

Fig. 11 Influence of cooling rate $T = G \times v$ on the primary “ e ” and secondary “ d_s ” dendrite spacings for 6 pure binary and ternary alloys with two Si-contents

different Magnesium and Antimony additions (in over-aged stage) show an excellent relation between measured R_m -values and the calculated R_m -values, using the OM-structures, which can be evaluated quantitatively. An example is given in Fig. 14.

The interaction of the alloying composition, the crystallization parameters, the OM- and SEM-microstructures without and with heat treatment, with the mechanical behavior of the cast material are shown in Fig. 15. These are the steps used for improving the commercial A357 alloy for a cast parts for Airbus and the AUDI A8. It should be noted here that the cooling down of the cast volume after finishing the solidification must be taken into account as a heat treatment, which is difficult to characterize because of the local differences in the temperature-time-run. All heat treatments influence the morphology of the Silicon phases in the eutectic volume and the solution as well as the precipitation of alloying elements in all α -Al-phases; but the values “ e ” and “ d_s ” of the dendrites remain unchanged!

Fig. 12 Eutectic microstructure influenced by the cooling rate T (or put into other words by the wall thickness of the castings)

Fig. 13 Examples for the relation between the microstructural parameters “ d_s ” and “ λ ” and the mechanical property R_m

ADDITIONAL KNOWLEDGE FROM THE μg -EXPERIMENTS IN SPACE

It has been shown that dendrite morphology and the eutectic phases are influenced strongly by the crystallization parameters. The best way to obtain precise correlations is to perform unidirectional crystallization experiments. The crystallization parameters “velocity of the solidification front” V_{EF} and the “temperature gradient at this front”

G_{EF} can be measured with high precision (Lit). An additional experimental variation (important to get much more information out of one experiment!) is the sudden stopping of this solidification front by quenching the residual melt volume. This provides much more additional information from a single experiment. Figure 16 shows the different modes of operation of the experimental equipment “GFQ” (Gradient Furnace with Quenching Devices) in the space shuttle: Fig. 16A illustrates the GFQ during unidirectional

Fig. 14 Relationship between the measured tensile strength R_m and, using the OM structures, calculated tensile strength R_m of unidirectionally crystallized two pure binary and eight ternary AlSi-alloys with different wt% of Si, ^[7,11] Sb [0.0, 0.4, 1.0] and Mg [0.0, 0.3]

Fig. 15 Interaction of alloy composition, crystallization parameters, OM- and SEM-microstructures with and without heat treatment with the mechanical values of cast parts

crystallizing the melt; the cylindric crucible containing the melt is fixed and the combination “furnace” (Q_{in}) and cooler (Q_{out}) are running with the velocity $V_{Furnace}$ along the probe. The solidification front SF is running “up” (in space there is no up and down!) with V_{SF} . In Fig. 16B, having enough solidified material for testing, the residual melt is quenched (Q_{quench}) by spray water from the cooler, which was pneumatic removed quickly at the position of the residual melt. The details of the quenched SF is explained in Fig. 16C: A section diameter of the stopped SF shows the unidirectional solidified and unidirectional quenched volume as well as center of the probe with the thermocouples (here four pieces) which were used to calculate V_{SF} and G_{SF} (lit).

With sufficient magnification of this SF, it is seen that it consists of two SFs! At SF I is the position of the top

of the dendrites and at SF II the interdendritic volume crystallized with eutectic morphology (consisting of α -Al-phases and Si-phases). In the interval between SF I and SF II, the dendrite-arms are coarsening to their final size at the point of SF II. Because every position Δx in this range is equal to a defined coarsening time t_c (to be calculated with V_{SF}), with one experiment the coarsening of dendrites (this means the increasing of value d_s) for different solidification experiments can be determined according Eq. 7.

$$t_c = \frac{\Delta x}{v_{SF} [s]} \quad (7)$$

where Δx = distance from the top of the dendrites (i.e.: I SF)

Fig. 16 Gradient Furnace with Quenching Devices (GFQ) schematic in the stage of unidirectional solidification (A) and during quenching the residual melt and freezing the solidification with front (B) (see also Fig. 7). (C) shows schematically a longitudinal section through the unidirectionally solidifying probe in the area of SF's position with the central points of temperature measurements and a magnification of the solidification front during dendritic solidification with the two SFs

Microgravity experiments were used to address the following questions:

1. Is there an influence of μg -conditions on the distribution of alloying elements in front of a planar SF in comparison to the situation on earth (i.e. 1 g-conditions)?
If yes, the information on the role diffusion and convection on the mass transport in relation to material structure is obtained.
2. Are there any differences in the dendrite morphology and eutectic morphology under μg -conditions?

If yes, a correlation between mechanical properties and metallographic morphology is possible which will permit the establishment of the necessary criteria to optimize alloy composition and solidification parameters for a specific application.

To address these questions, experiments were conducted with pure AlCu and AlSi alloys in the D1- and D2-Spacelab-Missions in 1985 and 1991 and the FOTON 10- and 11-Missions in 1996 and 1997.

The first knowledge which was to be gained was the influence of material transport at the SF. Figure 17 A shows that the metallographic section diameter through an

Fig. 17 Experimental results from the unidirectional solidification of a pure AlCu 0.3 alloy during the D1-Mission in 1985: (A) metallographic longitudinal section in the area of a planar SF (see also Fig. 7) with the structure of the rapidly quenched residual melt in front of the SF; (B) Micro-analysis of the Cu content behind (unidirectionally crystallized) and in front of the SF in two probes; the above under earth conditions and the lower under μg conditions crystallized under the same solidification parameters V_{SF} and G_{SF} (so-called reference exp.); the important difference is the amount of Cu concentration in front of the SF! (C) From (B) calculated the integral mass transport coefficients $D_{SF}^{int}(\xi)$ and $D_{SF}^{\mu g}(\xi)$ in front of the SF

unidirectional solidified AlCu0.3 alloy in the area of the quenched SF (the central channel with the thermocouples is on the upper line, the limitation to the crucible at the lower line). The unidirectionally solidified phase has no OM-visible structure, because the solidified volume is a single crystal. The quenched melt shows the morphology of rapid crystallized volume.

Crystallization experiments with the identical parameter V_{sf} and G_{sf} were performed under 1 g- and μ g-conditions (see Fig. 17B). By microanalysis, the distribution of Cu in the crystallization direction was determined: At the point of the SF, the discontinuous increase in concentration is related to the distribution coefficient K_0 which describes the difference in solubility of Cu in the solid and liquid phases of Al. The most important information is the changing in width δ of the so-called concentration amount in front of the SF. Figure 17B shows the value of δ is much higher under μ g-condition than under 1 g (9 mm in comparison to 3 mm).

Using the theoretical relationship between the concentration gradient and the “mass transport coefficient” $D^{integral}$, containing the mass transport by diffusion as well as by convection, the course of $D^{integral}(\xi)$ in front of the SF under μ g shows a strong decrease from about 4.5×10^{-5} to $0.8 \times 10^{-5} \text{ cm}^2/\text{sec}$. This is the opposite of what is observed under 1 g-conditions. $D^{integral}$ under 1 g originally exhibits at a greater distance from the SF a higher value than under

μ g ($6.0 \times 10^{-5} \text{ cm}^2/\text{sec}$) and the slope at the SF is only $5.5 \times 10^{-5} \text{ cm}^2/\text{sec}$ as shown in Fig. 17C. These super-elevations of $D^{integral}$ are caused by the gravity-driven convection in the melt on earth. It is a well known fact that the convection in liquid take the greater part of the mass transport in liquid. For the formation of structures during solidification of alloys, the integral mass transport in the vicinity of the SF is very important because of the necessity for decomposition within this part of the melt to obtain a synchronous growth of different phases for example like α -Al-phases and Si-phases in an AlSi alloy.

Figure 18 shows the calculated distribution of Silicon in the melt in the vicinity of the eutectic solidification front (II. SF). In a large distance of the top of the dendrites (I. SF) holds. $\text{grad } C_{si} = 0$ beginning with the primary crystallization of the α -phases, $\text{grad } C_s$ becomes $\neq 0$. In the interdendritic melt in front of the II. SF growth an axial as well as a lateral concentration gradient ($\delta C_{si}/\delta z \neq 0$ and $\delta C_{si}/\delta y \neq 0$), indicating that there is both an axial and a lateral mass transport.

Only by these mass fluxes, the extreme differences of Si-concentration in the α -phases and Si-phases of the eutectic volume can be created. Of course the high concentration gradients in the vicinity of the II. SF will be influenced strongly by every change of convection in the melt.

Fig. 18 Unidirectional solidification of AlSi alloy with the distribution of the alloying element Si in the Al-melt in front of the I and II Solidification front (semi-schematic). (A) Growth of dendrites and the eutecticum; the residual melt between the dendrites and in front of the I. SF is removed; (B) Alloying element distribution $C_{si}(Z)$ in the residual melt between the dendrites and in front of the I SF; (C) Three dimensional alloying element distribution $C_{si}(z; x)$ in front of the II SF (eutectic solidification front) with axial and lateral concentration gradients within the so-called “diffusion boundary layer” δ , corresponding to the α - and Si-phases of the eutecticum

In the case where the macrocrystallization parameters (v_{SF} and G_{SF}) are the same under μg - and 1 g-conditions, the distances of such decompositions becomes higher by the increased value of $D^{integral}$, influenced of buoyancy driven convection (1 g-conditions). This should have an influence on the eutectic crystallization as well as on the coarsening of dendrites, because both processes depend on the mass transport at the vicinity of the SFs.

From the D1-mission, the influence of μg -conditions on the growth and the coarsening of dendrites in a pure AlSi 7 alloy was determined: Fig. 19 shows the longitudinal and transversal metallographic sections in a probe crystallized under μg with the parameter $V_{SF} = 5.2$ [mm/min] and $G_{SF} = 15.9$ [K/mm]. The longitudinal metallographic section corresponds to the schematic picture of the SF in Fig. 16. The positions of SF I and SF II are marked as well as the region, in which the distance d_s of the second

dendrite arms growth up (coarsens). At different points in this region (this means at different coarsening times t_c), the distances d_s of dendrites were measured at different levels of newly produced metallographic planes (so-called "step-metallography"). These values were correlated with the coarsening times t_c . Additionally the primary distance "e" of the dendrites was evaluated on the transversal sections and correlated with the solidification parameters V_{SF} and G_{SF} , corresponding with the dendrite growth model of HUNDT [lit].

A summary of the dendrite arm coarsening of only two experiments under μg - and 1 g-conditions with nearly the same crystallization parameter are presented in Fig. 20: As expected, the d_s values increase with growing coarsening times t_c . Because of a better recognizability in the two identical diagrams, the metallographic determined values d_s of the mg-probe are marked in the upper, and

Fig. 19 Under mg conditions (D1-Spacelab-Mission) unidirectional solidified pure AlSi 7 alloy. (A) Metallographic longitudinal microsections in the area of the two SF of the probe; indicated are the positions of I and II SF and the area of coarsening of the dendrites between (the volume of solid phases increases from 0% at I SF up to 100% at II SF); at the left side: 100% unidirectionally solidified volume, at the right side: 100% quenched melt; (B) Metallographic cross microsection in the area between I and II SF; the stem of the dendrites are cut, between the dendrites the quenched interdendrital residual melt (black)

Fig. 20 Dendrite arm spacing d_s in dependence of the coarsening time t_c of unidirectional solidified pure AlSi 7 alloy under 1 g-(reference) and μg -conditions (during the D1-Spacelab-Mission); the crystallization parameters are nearly the same

the corresponding values of the 1 g-probe are marked in the lower diagram. For all t_c values, the μg -material shows lower values. These differences decrease with higher V_{SF} values, because of an increasing of the so-called micro-convection in the area of SF I and SF II. As already shown in Fig. 13A, mechanical strength increases with lower d_s values. Therefore, for this defined alloy, up to a coarsening time of 25 sec below the μg -slope, a so-called unattainable area of the spacings d_s can be defined. When developing a high strength material, this mg-line shows that better d_s values and in consequence better mechanical values, can not be achieved (see also Eq. 4)!

To explain the dendrite coarsening, the mass transport in the vicinity of dendritic surface is examined using Eqs. 4, 8 and 9. The material constant “M” contains among other material values the (atomar) diffusion coefficient D_L in liquid. Because the integral mass transport $D^{integral}$ influences the coarsening, different components of the $D^{integral}$ must be considered. If, besides the atomar D_L , a micro-convection in the vicinity of dendrite surface is active (which would be created by the negative volume jump ΔV during the phase transition from liquid to solid), an additional mass transport by the coefficient D_{AV} is possible. This kind of micro-convection is also called “advection” because of the flux in direction to the solid phases. Having additional buoyancy driven convection (mostly called macro-convection), there is a further component in $D^{integral}$, described by the coefficient D_{conv} . With these assumptions, the $D^{integral}$ we get for μg -conditions is:

$$D^{integral} = D_L^{atom} + D_{\Delta V} \quad (8a)$$

and for 1 g-conditions the term:

$$D^{integral} = D_L^{atom} + D_{\Delta V} + D_{conv} \quad (8b)$$

Because all other terms in “M” of Eq. 4 are constant, an integral M_{int} for μg conditions:

$$M_{int} = M_{atom} + M_{\Delta V} \quad (9a)$$

and 1 g conditions:

$$M_{int} = M_{atom} + M_{\Delta V} + M_{conv} \quad (9b)$$

is valid.

The measured values M_{int} for AlSi 7 alloy, processed during the D1- and D2-missions together with the calculated value M_{atom} (using the atomic diffusion coefficient D_L^{atom}) permit the determination of $M_{\Delta V}$ for different crystallization velocities V_{SF} under μg -conditions (see Fig. 21A) and further to determine the variation of M_{conv} , using the measured (constant) M_{int} under 1 g-conditions (see Fig. 20B). The values for $M_{\Delta V}$ are only dependant from the alloy and the crystallization parameters v_{sf} and G_{sf} (not from the buoyancy forces).

There is also an influence of the eutectic structures on the mechanical behavior. The influence of gravitational accelerated convection can be recognized under μg too.

Figure 22 provides an example of crystallization experiments conducted during the FOTON-missions. The pure near-eutectic AlSi 11 alloy was solidified under μg - and 1 g-conditions with a nearly constant temperature gradient G_{sf} (about 15 [K/mm]) and three groups of v_{sf} -velocities about 0.5, 1.0 and 1.9 [mm/min]. The metallographic pictures show the parts of the interdendritic eutecticum (without the bordering dendritic α -phases). It is obvious that with increasing v_{sf} the microstructures of the eutectica becomes more filigreed and additional that in comparison with the structures of the μg -probes the Si phases of the 1 g-probe are much rougher. Because of the strong differences in strength and ductility of the α -Al-phases and the Si-phases, this change in eutectic morphology influences the mechanical behavior also (Eq. 6). In the following example (Fig. 23), the eutectic spacings λ between the Si-phases were evaluated from the pure AlSi 7- and AlSi 11-probes, which were processed during the SPACELAB- and FOTON-missions. In the diagram, the correlation of the spacings λ with the cooling rate T (between T_L and T_E) of the different alloys are presented in an double logarithmic scale. The absence of buoyancy-driven convection under μg -conditions for all crystallization parameters also creates a reduction of the interdendritic eutectic spacings λ . From these results, the absolute minimum of the spacing λ is also defined by the “unattainable area” in this diagram. Therefore, these results show that the maxima of the mechanical values which can be achieved be

Fig. 21 Influence of the solidification front velocity V_{SF} on the integral and the partial coarsening parameters M (see Eq. 7 under μg - and $1g$ -conditions)

Fig. 22 Influence of μg - and $1g$ -conditions on the morphology of the eutectic of the near hypoeutectic AlSi 11 alloy, crystallized with three velocities V_{SF} and uniform temperature gradient G_{SF} in front of the SF; to be compared the $1g$ -reference experiments to the assigned μg -experiments

minimizing the λ spacing in eutectic volume is restricted by the line of μg .

An additional example of the impact of gravity driven convection on the eutectic morphology is illustrated by the influence of cooling velocity T in a wide range ($2 [K/min] < T < 720 [K/min]$) during solidification on the spacing λ in unidirectionally solidified AlSi 11 probes, described in Fig. 24: The hypo-eutectic alloy should create, according to the Al-Si-equilibrium diagram, a dendritic and a eutectic crystallization! As to be seen from the graph $\lambda(T)$ is

interrupted at a cooling velocity T of about $10 [K/min]$. An explanation is given by the change of the eutectic volume $f_{EU} [\%]$ in dependence of T : At the same value for the cooling velocity, the value of f_{EU} jumps from 100% to a value of about 90%. This means that, having $T < 10 [K/min]$, the volume crystallizes only in an eutectic mode and, under $T > 10 [K/min]$, an additional dendritic volume crystallizes beginning with about 10% and showing a linear increase (in the double logarithmic scale!) up to a value of 30 vol%. Further experimental and theoretical work (Lit) shows that

Fig. 23 Influence of the cooling rate T on the morphology of a hypo- and near-eutectic AlSi alloys (here on the eutectic spacing λ), unidirectionally crystallized under μg - and 1 g-conditions in a double logarithmic scale (results from D1- and D2-Spacelab Mission). The values of λ grown under mg are smaller than under earth conditions for all crystallization parameters. The area beneath the graph for the mg-results from the boundary of the unattainable area of λ ; this means that, using such alloys and the tested crystallization velocities, no smaller λ values can be obtained and that aiming at high mechanical values no better results can be reached!

the buoyancy-driven convection in the melt will be suppressed by the dendrites behind the SF I with decreasing primary dendrite arm spacings “e”!

But with increasing solidification velocity, microscopic convection rises. As a first approximation, it can be assumed, that the sum of convection remains constant. An additional convection term occurs in the melt between SF I and SF II: The increasing volume of the dendrites behind their tips causes a so-called micro-convection. The change of liquid into solid volume produces a negative volume change ΔV causing an additional intensive convection. This ΔV -convection increases the integral mass transport coefficient “ D^{int} ” in liquid. Therefore the spacing l increases with appearing of the dendrites. The value of λ is useful as a scale for the quantity of “ $D^{integral}$ ”. Figure 25 shows the change of “ $D^{integral}$ ” in dependance on the cooling velocity T for the solidification of the AlSi 11 alloy. Because the atomar diffusion coefficient D_L^{atom} is a material constant and only influenced by the temperature, the “ $D^{integral}$ ” is related to D_L^{atom} in the ordinate of this diagram.

The sum of “ $D^{integral}$ ” consists with the change of the cooling rate T of a constant value of D_L^{atom} , an increasing mass convective transport D_{conv} by buoyancy driven convection and, passing the threshold of $T = 10$ [K/min], the additional mass transport $D_{\Delta V}$ by the micro-convection from the volume change ΔV .

Another important point is the geometry of the silicon phases: Fig. 26 shows that the growth of the Silicon

phases during eutectic crystallization is different. A lamellar geometry (a), a mostly angular geometry (b), and an angular geometry with primary Si phases (c) is shown. The dependence of all these structures on the Si-concentration and the velocity of crystallization v_{SF} is shown in Fig. 27 (Lit Lit). The different details of the Si-geometry occur in one eutectic area, which means that local differences in Si-concentration and/or v_{SF} during the eutectic solidification may exist. An important result of our μg -experiments is the absence of any influences from mg- or 1 g-conditions on these geometries of the Si-phases.

To illustrate the influence of the Si-concentration during eutectic solidification, the quenched solidification front of two AlSi alloys with 12.4 and 13.2 w% Silicon are provided in Fig. 28: The unidirectional solidified volume without any heat treatment (direct behind the quenched SF) clearly shows the change of more plate-like to complex regular geometry.

The subtle details of these structures to explain the crystallization kinetic and to calculate the mechanical material behavior rely on a two-dimensional information!

Fig. 24 Influence of cooling rate T on the eutectic spacing λ of an unidirectionally crystallized AlSi 11 alloy; the discontinuity of the graph at $T = 10$ K/min is caused by the transition from a pure eutectic crystallization of the AlSi11 alloy to an eutectic and a dendritic crystallization. This is documented by the upper diagram with the change of “volume fraction” of eutectic f_{EU} from 100% to about 85% at the same cooling rate

Fig. 25 Ratio of the integral mass transport coefficient D_L^{integral} and the atomic mass transport coefficient D_L^{atom} (the real diffusion coefficient) depending on the cooling rate T for μg - and 1 g -conditions. Under μg the values of D_L^{integral} are influenced up to $T < 10\text{ K/min}$ only by the (constant) real diffusion coefficient D_L^{atom} , having $T > 10\text{ K/min}$ an increasing mass transport from the volume jump $D_{\Delta V}$ enlarges the D_L^{integral} -values. Under 1 g condition these values become superimposed additionally over the whole range of T by an increasing mass transport D_{conv} from the buoyancy forces

This poverty in information should be explained by a comparison of two- and three-dimensionally metallographic structures of a modified A357 alloy with different stages of heat treatments (Fig. 29): The two-dimensional OM pictures show the intimate structures beginning with the stage “as cast” and with two solutionizing times. As already mentioned, a change of the dendrites does not occur, but the morphology of the eutectic Si-phases becomes a more spherical morphology with increasing heat treatment time. A comparison of these structures with the three-dimension pictures, taken by an SEM, after a so-called “deep-etching” (the $\alpha\text{-Al}$ -phases are removed at the metallographic plane) shows that Si-balls of the OM picture (Fig. 29B) in reality are cylindric volumes and that a visual comparison to the SEM is possible only after a heating time 50 hr of the visual impression seems to be given only after a heating time of 50 hr (see Fig. 28C). This inaccurate comparison results in a so-called unsharpness in explaining the correlation of structures and mechanical behavior. To overcome these difficulties an important tool has been missing until now: the quantitative structure determination from three-dimensional metallographic pictures.

DEVELOPING OF HIGH STRENGTH CASTINGS USING RESULTS FROM μg -EXPERIMENTS

The first example describes a so-called corner fitting for the plane “AIRBUS”. Until now, this part was milled with differences in the wall thickness from wrought high strength Al alloy sheets. After modifying the alloy, optimizing the crystallization parameters according (Figs. 15 and 3) and using a kind of unidirectional crystallization (so-called SOPHIA process; Lit) this part was cast with the demanded local mechanical values (Fig. 30). The important condition was to guarantee a minimum of R_m and $R_{p0.2}$ as well as a maximum of fracture elongation A_5 for all wall thicknesses (it means different cooling rates T) of the corner fitting.

The microgravity experiments have shown which limiting values like dendrite arm spacing d_s and which minimal sizes of the eutectic phases, for example the average spacing λ of the Si-phases, can be achieved under utmost conditions. The objective of this work was to obtain an extensive range of the given technical possibilities to optimize (about 80% to 90%) the microscopical structures only with one parameter. Only then, any of the remaining

Fig. 26 Influence of the Si content in near eutectic AlSi alloys (a) AlSi11.2, (b) AlSi13.2, and (c) AlSi13.8 on the morphology of the Si-phases; (a) lamellar Silicon with cellular/dendritic α_{Al} -phases; (b) mostly angular Silicon; (c) angular with additional primary Silicon; there is no influence of μg on these Silicon-morphologies!

Fig. 27 Definition of the different Silicon-morphologies “angular”, “lamellar”, “plate-like”, “complex regular” and “primary” of near eutectic AlSi alloys (AlSi 10.3; AlSi 11.2; AlSi 12.4; AlSi 13.2 and AlSi 14.6) defined from one eutectic volume and corresponding with the above defined alloys and combined with the $C_{Si}(v_{SF})$ -diagrams after R. Elliott (the dots in the diagrams characterize our solidification experiments)

parameters should be changed. These parameters include: chemical additions to the alloying elements, crystallization parameters like v_{SF} , G_{SF} and convection conditions in liquid ahead of the solidification front, and consideration of the macroscopic conditions of the casting processes like “VAKURAL” or “SOPHIA”. For the same cast part (with an equal area of wall thickness) the crystallization velocities increase using the “SOPHIA”-process (this causes low e , d_s and λ -values).

The choice of unidirectional solidification also avoids shrink holes and pores. Figure 31 shows the area of the SOPHIA process in the function $d_s(T)$. Conventionally

cast parts contain the higher d_s -values. The comparison of conventional with “SOPHIA” castings shows (for all wall thicknesses in the “corner fitting” from 2 until 12 mm) together with the optimized A357 alloy composition and the optimized heat treatment, the best mechanical values R_m , R_p and A_5 for “SOPHIA” (Fig. 32).

The “flap track” “SOPHIA” casting for the AIRBUS, cast with the conventional A357 alloy and with conventional heat treating, has larger metallurgical structures (for example d_s and λ) but shows over the wall thickness from about 8 to 50 mm lower, but also well-balanced mechanical values, caused by the casting method (Fig. 33).

Fig. 28 Example of quenched solidification front in unidirectionally crystallized AlSi 12.4 alloy ($v_{EF} = 0.17$ mm/min, $G_{EF} = 10.7$ K/min) with more angular Si-structures and AlSi 13.2 ($v_{EF} = 0.13$ mm/min, $G_{EF} = 10.3$ K/min) with more complex regular Si-structures behind the quenched SF

In the aircraft industry, the so-called “Quality Index” “Q” was created to get an useful combination of the two important mechanical values tensile strength R_m and fracture strain A_5 for materials (Eq. 8).

$$Q = R_m + 150 \log(A_5) \quad (8)$$

Figure 34 shows the Q value of SOPHIA castings and especially the optimized SOPHIA castings using μg -results in the diagram R_m as a function of A_5 . The diagonal lines describe the course of constant Q values. The highest Q value represents the most useful quality for airplanes.

An example from the automotive technique is the optimization of the mechanical properties of a VACURAL die cast part with an alloy AlSi10 Mg0.30. Figure 35 shows the AUDI A8 “space frame” with the pressure die castings “corner fitting” for the connection of the extruded shapes. For these complex parts with a large area of wall thickness, the unidirectional casting with strong convection was selected and the morphologies of the eutectic and dendrite volume were minimized.

The following procedures were conducted: Solidification experiments (unidirectional!) with the original die cast parts to correlate microstructural parameters and mechanical behavior. These experimental results permitted the identification of an optimum alloy composition and optimal crystallization parameters, to yield useful mechanical properties which were then used to develop

Fig. 29 Comparison of the metallographic structures of a technical AlSi 7 alloy (modified A357 with 1% Cu), as cast and heat treated, in two and three dimensional view (OM- and REM-pictures). (a) as cast; (b) heat treated at 535°C over 1 hr; (c) heat treated at 535°C over 50 hr

Fig. 30 Example of a casting for the AIRBUS (so-called “corner fitting”) with its position in the construction

Fig. 31 Dendrite arm spacing d_s influenced by the crystallization velocity T in a modified A357 alloy. The parts were cast as “corner fitting” using different conventional (unidirectional) methods as well as using the special casting method “SOPHIA”; as to be seen crystallization velocities from about 50 to 200 K/sec (this means for wall thicknesses from 2 to 12 mm) the values for d_s are here the best using “SOPHIA”

the conditions of VACURAL die casting process. The castings in the space frame must meet extreme quality safety demands with high rates of R_m and R_p as well as a fracture strain A_5 which must be high as possible in each location of the casting. In case of a crash, enough deformation energy must be adsorbed by the deformation of these castings.

Fig. 32 Comparison of the main mechanical values taken from parts of the “corner fittings” with different wall thickness using conventionally A357 alloy with conventional casting and heat treatments with the values from “corner fittings” produced using the modified A357 alloy, the casting method “SOPHIA” and a modified heat treatment T6opt

Figure 36 A shows the dendrite arm spacing d_s depending on the cooling rate during crystallization in detail. Two AlSi-alloys were unidirectionally crystallized and the alloy with the higher Si-content additionally VACURAL-cast. The functions $d_s(T)$ are nearly the same. Since there is the demand for different wall thickness

Fig. 33 “Flap Track Casting” for the AIRBUS using conventionally A357 alloy and the “SOPHIA” method (max length 850 mm, wall thickness from 4 to 50 mm); the graphs below show the dependant of tensile strength, yield strength and elongation from the wall thickness (here unknown correlation with the crystallization velocities)^[14]

(i.e. “modoli”), a sufficient small d_s value also in thick zones of the cast part can be generated by a precise choice of combination of the alloying elements together with the control of the cooling- and convection-conditions (here VAKURAL). The calculated cooling velocities T for all areas of the “corner fitting” show values between 600 and 4000 K/sec. The important sector of the dendrite arm spacings d_s from about 7 to 10 mm from Fig. 36A is correlated with the mechanical values R_m , R_p and A_5 in

Fig. 36B. To get high enough ductility values, the d_s values were created to be $< 9 \mu\text{m}$ by crystallization velocity and convection.

An integrated scheme for the development of optimized castings is provided in Fig. 37. The initial step is determining all structural parameters of the cast part which must be optimized. Secondly, the corresponding crystallization parameters must be determined. After improvement of the microstructures and comparison with the results of

Fig. 34 Classifying of different castings in the “Quality Index Q” diagram. This kind of presentation gives, for the air industry, a useful combination of the values R_m and A_5 ; the best qualified materials show the highest Q-value

mg-experiments the adaption of the optimized parameters is performed to obtain optimized castings.

SUMMARY

The heaviest deficit in developing high strength castings is the implementation of scientific knowledge. The enlarged know-how about the mass transport during crystallization by the results from mg-experiments gives the possibility to recognize the limits in influencing the microstructures as well as the separated influence of the crystallization

velocity and the macroconvection ahead the solidification front. The areas of unattainable metallographic values, for example the dendrite arm spacings d_s and the eutectic spacing λ , are the limit for getting optimized structures for a defined alloy. Because of the strong effect of the metallographic structures on the mechanical behavior of materials, this is essential for all technical castings. From this it is possible to optimize all parameters for castings, like the alloying elements, the crystallization parameters (including the convection), the macroscopic kind of (industrial) processing the crystallization and, finally, the heat treatment of the cast parts adapted to the microstructures.

Examples from the automotive and aviation industry have been provided which illustrate the value of μg crystallization studies in industrial process optimization.

Micromachining of Aluminum Alloys

Ann Rumsey and Muhammad Jahan

Mechanical and Manufacturing Engineering, Miami University, 650 E High St, Oxford, OH, 45056, United States

Abstract

This article provides a comprehensive overview of the machining of aluminum alloys, composites, and ceramics at micro scale. All major aspects of the micromachining of aluminum alloys including process descriptions, key research findings, applications, major challenges, and guidelines for future research have been covered in this article. Based on the literature, conventional micromachining processes, such as turning, milling, grinding, and drilling, have been found to be suitable for machining most of the cast and wrought aluminum alloys. On the other hand, nonconventional micromachining processes were approached for the micromachining of aluminum metal matrix composites and alumina ceramics. Some challenges and aspects in the area of micromachining of aluminum alloys that need future considerations are burr formation, tool wear, surface finish, microstructures and properties changes, and process development for advanced and hybrid micromachining.

Keywords: Aluminum alloys; Challenges in micromachining; Conventional micromachining; Micromachining; Nonconventional micromachining.

INTRODUCTION

Aluminum (Al) is one of the most important industrial metals widely used in automotive, aerospace, structural, and many industrial applications. Pure aluminum is very soft, lightweight, and ductile, and thus, a range of alloying elements are added to impart the desired properties, such as strength, toughness, corrosion resistance, and other physical properties. The most important alloying elements added to aluminum are silicon (Si), magnesium (Mg), manganese (Mn), copper (Cu), and zinc (Zn). Zn and Cu are added for increasing the strength, and Mn, Mg, Si, and Fe are added for improving the strength, ductility, and toughness, whereas titanium (Ti), boron (B), zirconium (Zr), chromium (Cr), nickel (Ni), bismuth (Bi), and lead (Pb) are some other additional elements used to impart special properties to the aluminum alloys.^[1] The aluminum alloys are classified based on the alloying elements and the type of strengthening mechanism. There are many different classification systems such as American standard (AA), European standard (ISO), Swedish standard (SS), and Norwegian standard (NS); however, AA standard is more common, and the AA designation classifies the alloys by major alloying element(s). In addition, a distinction is made between wrought and cast alloys, and between non-heat-treatable and heat-treatable alloys.

Besides standard aluminum alloys, there is development of new aluminum metal matrix composites (MMCs). Aluminum MMCs are mostly the aluminum alloys with

reinforcement of other materials to improve the physical and mechanical properties of the alloy. The addition of reinforcements into the metallic matrix improves the stiffness, specific strength, wear, creep, and fatigue properties compared to the conventional engineering materials.^[2] The most commonly used reinforcements in aluminum MMCs are silicon carbide (SiC), aluminum oxide (Al_2O_3), and boron carbide (B_4C).^[3] SiC reinforcement improves the tensile strength, hardness, and wear resistance; Al_2O_3 reinforcement increases the compressive strength and wear resistance; and B_4C increases the hardness of aluminum-based MMCs.^[3–5] The major applications of aluminum-based MMCs are in aerospace, aircraft, automotive, and structural industries.^[2–8]

Another development of the aluminum family is the alumina-based ceramics. Alumina-based ceramics are used in a wide range of structural applications with energy-tense service conditions due to their high hardness, wear, heat, and chemical resistance.^[9] Some of the important applications of alumina ceramics are the production of critical wear-resistant machine parts, dry friction pairs, jet-forming nozzles for hydro abrasive cutting, cutting tool inserts for dry machining, and protective coatings for metallic parts, high-voltage insulations, armor applications, and so on.^[9–11] There are many varieties of alumina-based ceramics and researchers are investigating in different ways to improve the properties of alumina ceramics by adding other oxides or reinforcement particles in the alumina matrix. For example, doping of MgO, TiO_2 , and ZrO_2 in alumina ceramics provides higher abrasive–erosive wear resistance.^[12] Some

researchers have reported that insertion of reinforcements such as glass, carbon nanotubes, and metal nanoparticles can further improve the mechanical and physical properties of alumina-based ceramics.^[13–15]
